No. 1 was distilled wet, Nos. 2 and 3 dry. After this, the charges were dried, and returned to the closet, and used again before being re-burnt. Nos. 8, 9, and 10 are complete analyses; and what is deficient in the others is calculated from these. A portion of the ammonia comes over combined with acetic acid, which is separately shown, and also the acetic acid as acetate of lime. The average results per deposit and per cent of wet and dry excreta are also shown. The composition of several of the resulting chars, and the increase per cent of the several ingredients, are shown in Table E. After No. 3, the compositions are pretty similar; and this may be taken, therefore, to be the char from excreta. The char commenced with was only 3 lbs., or 48 ozs., to which 18 ozs. were afterwards added, the total amount employed being 66 ozs. At the end of the experiment, it amounted to 123 ozs., 57 ozs. being derived from the excreta; and yet this small original stock served 181 uses of the closet and absorbed 808 ozs. of wet excreta, having been dried and re-used seventeen times, and re-burnt ten times. It increased about 66 per cent in density, then remaining constant, but was in every respect better adapted for the closet, and improved by the treatment, the charge being still under 8 ozs. at the end of the experiment. The distillation yielded over 38 ozs. of sulphate of ammonia, or nearly 7 per cent of the wet excreta. I propose that the mixture should be dried and re-used five times before being re-burnt: this has not been done in these experiments, as I was impatient for results. Where this is done, a considerable quantity of gas is given off in the distillation, and, from the large amount of fatty matter, it possesses considerable illuminating power. This fatty

matter is characteristic of excreta, and is shown in the large quantity of tar yielded in the distillation—over 9 per cent; wood yielding only 10 per cent, and coal 12 per cent. The yield of ammonia equals 31 per cent of sulphate, showing this to be a most prolific source. It is remarkable that the re-burning shows the products of distillation of vegetable matter—acetic acid, for instance, combined with those from animal matter, as ammonia, for example, arising from the mixed nature of the human food. These experiments were conducted on excreta from poorly-fed lads: amongst good livers, the nitrogen, phosphates, and fatty matter would probably be much increased. These tables represent, therefore, the minimum yield. Taking these data, 1 ton of char which had been used five times would yield, allowing 15 per cent moisture, 48 cwts. of manure, containing nitrogen equal to 18 per cent sulphate of ammonia, 15 per cent phosphate of lime (reckoned as soluble), and 7½ per cent sulphate of potash, and worth £7 per ton. Its cost for char, £2, and for cartage, 5 tons in and 10 tons out, equal 15 tons at 1s., equal 15s. If advisable to hasten its sale by drying, it would cost 10s. more, the total cost being £3 5s., or about 28s. per ton. If re-burnt and returned to the closet, the re-burning would cost 3s. 6d. per ton, or 8s. 6d., and yield over 8 cwts. sulphate of ammonia at 16s., equal £6 8s. less cost of acid, and, allowing 10 per cent for moisture, 33 cwts. of char, partly to return to the closet and partly for sale as manure, and worth about £5 per ton. I think these data are sufficient to show that this process presents the means of recovering the total value of the excreta. In addition, there are other unexpected sources of further profit; for 100 tons of dry, solid excreta yield 9 tons of tar and 4 tons of acetate of lime, besides a considerable quantity of richly-illuminating gas.

I have brought this subject before the Section in the full belief that it must some day become a chemical question; and I maintain that engineers have shown their incompetence to deal with it alone. Water-closet excreta is now admitted to be the worst poison to put into our rivers; and why should such volumes of water be thus employed for such pollution? If this large amount of water be unnecessary, if, moreover, it be grossly wasteful and fearfully prejudicial to health, it becomes our duty to discuss any other method by which chemistry may be made available to secure that which has hitherto been lost. I repeat here my conviction expressed in a former paper—that "Every system of sewage, to be permanent, must give back to the soil that which in our food we have taken from it; and the mere ridding ourselves of a valuable fertiliser simply on account of difficulty in dealing with it is unworthy the enlightened spirit of our age." At the same time, I admit that considerations of health must always precede those of wealth in this respect, and no system need be spoken of against which there is a whisper of suspicion on this point.

Nothing can be said against the dry-closet in this respect. It has already become a recognised institution. It presents the best means at present known of confining a nuisance within its proper limits, instead of distributing it amongst our neighbours, and therefore merits our patient consideration.

There can be no doubt that, for country houses, the earth-closet is free from objection; but there is also no doubt that, with earth, it could not be applied to large towns; but, with the modification proposed, its use will be profitable in direct proportion to the size of the town. By its use we are enabled to store the manure for the farmer, and dispose of it when he wants it, and not whenever we want to get rid of it, which materially affects the market price.

While, therefore, there can be no doubt of the healthfulness of this process, I believe enough has been proved in this paper to show that the gradual introduction of char-closets will become national stepping-stones to health and wealth.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

In accordance with the generally expressed wishes of our friends and readers, we have effected arrangements to enable us to give, under the above heading, notices of EVERY CHEMICAL PAPER IN THE WORLD, *as soon as possible after publication. Whenever possible, these notices will appear in the form of carefully prepared, although necessarily brief, abstracts; as respects papers either too long or too abstruse to render condensation possible, their titles will be chronicled; and in all cases accurate reference will be made to the original publication. The two half-yearly volumes of the* CHEMICAL NEWS, *with their copious indices, will therefore be equivalent to an English edition of the "Jahresberichte," with the additional advantage of keeping the readers week by week on a level with the latest advances of science.*

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, October 11, 1869.

The first paper is by M. Duhamel, on the—

Principles of the Science of Forces.—This is the third portion of a work the author is occupied with, the two former parts treating of the science of numbers and the science of space. We mention the title because the writer is an excellent authority on this and kindred subjects.

Expansion of Gases.—M. Victor Regnault.—The author refers, first, to his series of experiments on this subject made since the year 1842, and states that he believed he had found a method to determine with the same apparatus, first, the specific heat of a gas under constant pressure and variable volume; and, secondly, its specific heat under constant volume, while the pressure varies so as to leave the volume (bulk) constantly the same. Next follows the description of a series of experiments, and conclusions drawn therefrom, made at a later date; while the lengthy memoir is devoted to what the author calls simple expansion, or static expansion—that is to say, the expansion of a gas while at rest, when, by any exterior force, the space it occupies is made larger and the gas comes to rest again after the expansion. The other kind of expansion, called dynamic, is, when a gas, either while at rest or moving, expands while passing through any opening, and escapes into the calorimetric apparatus with all the velocity it has acquired. This memoir is of very great length, and the subject treated with the well-known ability of this eminent author, who, it will be remembered, satisfactorily settled the theory of the pressure of steam under various conditions.

Maximum of Force of Electro-Magnets.—M. du Moncel.—A mathematico-physical treatise.

Electricity Developed by the Dissolving of Salts in Water.—M. Raoult.—The author says the dissolution of a salt in water is a complex phenomenon whereby we distinguish—1st, the *fusion* (melting), or *disintegration* of the salt, whereby heat is absorbed; 2nd, the *diffusion* of saline molecules in water, which also absorbs heat; 3rd, the *combination* of the salt with water, whereby heat is set free. The author then states that the conditions alluded to under Nos. 1 and 2 do not produce any electricity, but that, on the other hand, the combination of a salt with water certainly does give rise to an electric current, to prove which the author records a series of experimental results.

Condensation (Occlusion) of Nascent Hydrogen.—M. Raoult.—The author states that the small cubes of metallic nickel ordinarily met with in commerce, and which are rather porous, absorb (condense) at least 165 times their bulk of nascent hydrogen under the same conditions as palladium does. The metallic nickel employed was not pure, but was found to consist, in 100 parts, of:—Nickel, 88·4; copper, 8·1; iron, 2·7; arsenic, 0·8. Perfectly pure, but yet porous, nickel exhibited the same phenomenon; but not so the compact refined, rolled, or hammered nickel.

Analysis of Raw Yellow Silks of Commerce.—M. Mène.—A series of figures exhibiting the results of the elementary and proximate analysis of a great many varieties of raw silks obtained from divers silk-producing countries of the world. The specific gravity appears to vary between 1·670 and 1·80. The elementary organic analysis is not of much use, since silk in raw state contains:—Substances soluble in water, partly nitrogenous, partly carbohydrates; fatty, resinous, and colouring substances soluble in alcohol and ether; and, lastly, the genuine fibre, a nitrogenous compound again soluble in acetic acid. It is impossible here to quote a lengthy series of figures, which is the less required since it is a well-known fact that raw silk varies considerably, according to to the food, climate, and condition of the worms which secrete this substance.

Researches on Lydine.—M. Guyot.—The author states that when he tried to prepare a certain aniline colour according to the directions given by M. Stark, by treating acid chlorhydrate of aniline with ferricyanide of potassium, and by treating the precipitate with oxalic acid, he did not succeed in obtaining a red colouring matter, as stated by M. Stark. The author obtained, however, a beautiful violet colour, which he calls *lydine*, by the following process:—100 grms. of fuming hydrochloric acid, diluted with 120 c.c.; this mixture is poured into a solution of 90 grms. of the ferricyanide of potassium (so-called red prussiate) and 850 c.c. of water; next boiled for an hour and a half, and cooled. The precipitate which has been formed is washed by decantation, and re-dissolved in a nearly saturated aqueous solution of oxalic acid, whereby the violet colour is immediately developed; and, on evaporating this solution to dryness, a paste soluble in water is obtained, which is the extract of lydine. The acid solution just alluded to may serve for dyeing silk and wool without mordants; cotton mordanted with alumina assumes the dye, also, readily. Pure lydine is a beautifully blue violet-coloured powder, soluble in alcohol, difficultly soluble in ether and benzol, and insoluble in water.

Elimination of Lime from Natural Waters by means of Oxalic Acid.—M. Monier.—Upon 100 litres of water from the Seine, 20 grms. of oxalic acid are used, previously dissolved in distilled water; an abundant precipitate is formed; after the lapse of twenty-four hours, some 85 litres of water are carefully drawn off by means of a syphon; and, on analysis, it was found that fully two-thirds of the mineral matter contained in the water had been precipitated, and the water rendered very soft. It is clear, however, that the use of oxalic acid could not be made applicable on the large scale, for various reasons, even if the acid itself was less expensive.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 14, 1869.

This number contains the following original papers:—

Preparation of Crystallised Silica by the Dry Way.—M. Rose.—After referring to the experiments made on this subject by himself and others, the author states that he resumed his researches on this subject at the Royal Porcelain Manufactory, at Berlin, and was aided in his work by MM. Elsner and Herzog. The mineral, named adular, was fused with three times its bulk of salt of phosphorus. The fused mass was dissolved in dilute HCl; and perfectly well-defined crystals, though of very small size, were obtained; the specific gravity of these crystals varied from 2·311 to 2·317 for a series of experiments made with the same substances. The silicic acid thus obtained has the properties of tridymite. Another series of similar experiments, made with very pure amorphous silica, yielded, again, microscopically-small crystals; but their shape did not differ from those obtained with adular. A large number of similar experiments were made with different fluxes, leading to the result that the preparation of crystallised silica by the dry way, or fusion process, has as yet only succeeded in the production of crystals shaped like tridymite and opal. The author is engaged in further investigations on this subject.

Bases of the Picoline Series.—M. A. Baeyer.—Picoline is obtained when tribromallyl is strongly heated with alcoholic solution of ammonia. There is, at first, formed dibromallylamine, and, next, picoline. Aldehydine, a newly-discovered base, prepared also by this author, is homologous with picoline. During the formation of aldehydine, there are formed oxytetraldine, oxypentaldine, and also collidine.

On Cinchonine-Chinoline.—M. Lubavin.—When chinoline is heated for some days, at 100°, with fuming sulphuric acid, the result is the formation of chinosulphuric acid, $NC_9H_6.SO_3OH$. This substance is difficultly soluble in cold water, more readily so in hot water and alcohol, and insoluble in ether. When this acid is heated, along with water and bromine, at 100°, there is formed a bromated chinoline, and, not simultaneously, a bromated sulpho acid. When chinoline is treated with a concentrated solution of caustic alkali, a greenish blue-coloured substance is produced, which is also produced when cinchonine is so treated; on addition of water, this colour disappears, and there is then formed a brown-coloured amorphous substance.

Products of the Distillation of Raw Spirits.—MM. Krämer and Pinner.—The authors had an opportunity of investigating the different products which, by the distillation of spirits—that is to say, the manufacture thereof—from grain, are formed, and can be separately collected, owing to the perfection of the rectifying apparatus in use, on the large scale. Among these substances are prominent—aldehyde, acetal, propyl-alcohol, butyl-alcohol, acetic ether, fusel oil, and a mixture of different substances.

On Monobromobenzolsulpho-Acid.—M. Genz.—The acid just named has been first prepared by M. Couper. The author has obtained it by placing benzol-sulpho acid, bromine, and water in sealed tubes, and heating to 150° in an oil-bath for about five hours. After a lengthy process of purifying, a substance was obtained of which the baryta, copper, and ammonia salts were investigated, and the acid itself set free from the copper salt, by means of sulphuretted hydrogen. The acid so prepared exhibits deliquescent crystals. The baryta salt, $Ba(C_6H_4BrSO_3)_2+H_2O$, is soluble in hot water and insoluble in alcohol. The copper salt, obtained from the baryta salt by double decomposition with sulphate of copper, crystallises readily, and is soluble in water and alcohol.

Nitro and Amido Derivatives from Cyanide of Naphthyl.—M. A. Welkov.—The author prepared, from a cyanaphthyl, $C_{11}H_7N$, a nitro-compound, which crystallises from its alcoholic solution, and is composed of $C_{11}H_6N_2O_2=C_{10}H_6(CN)(NO_2)$. From that compound, the amido base was obtained, by means of a reducing agent, the hydrochlorate of which has the formula $C_{11}H_9N_2Cl$.

Some Derivatives from Bromide of Aniline.—M. W. Otto.—Dibromated diphenylsulpho-carbamide, $C_{18}H_{10}Br_2N_2S$, a solid crystalline substance, soluble in alcohol, fusing at 178° and subliming at 200°; insoluble in water, both hot and cold, also insoluble in ether, and readily soluble in hot alcohol. Bibromated diphenyl-carbamide, $C_{18}H_{10}Br_2N_2O$, also a solid substance, sublimes at about 222°, with-

out entering into fusion. Quadribromated diphenyl-carbamide, $C_{13}H_8Br_4N_2O$, again a solid crystalline substance, difficultly soluble in any neutral menstruum. Bromated phenyl-senföl (essential oil of mustard), C_7H_4BrNS, a crystalline substance exhibiting the smell of aniseed, fusing at 60°, and soluble in alcohol and ether.

On Isomeric Xylidine.—Drs. A. W. Hofmann and C. A. Martius.—This paper, and the following—

On Naphthaline Red—Dr. Hofmann—are not well suited for abstraction with due regard to the contents and the labour of the authors.

Action of Cyanogen upon Anthranilic Acid.—M. Griess.—The author, after having briefly reviewed his former investigations on the action of cyanogen upon amido-benzoic acid, treats, in this paper, at very great length, on the action of cyanogen upon a compound, $C_{10}H_{10}N_2O_3$, being a product of the action of cyanogen upon an alcoholic solution of anthranilic acid left standing by itself for several days. We regret that it is impossible to enter into further abstraction of this paper, owing to the fact that we should be obliged to reproduce so large a number of formulæ.

Description of an Apparatus for Exhibiting Combustion Experiments in a Lecture-Room.—M. Kekulé.—Without the reproduction of the two woodcuts added to this paper, it is not possible to make the description properly understood.

On Ethyl-Benzoic Acid.—MM. Thorpe and Kekulé.—The authors and M. Fittig, having, some years since, synthetically prepared ethyl-benzoic acid from ethyl-benzol, the question treated of in this paper is, to decide whether the ethyl-benzoic acid obtained in this manner is identically the same as that obtained by the last-named party, by means of the oxidation of diethyl-benzol. The result of a carefully-instituted comparative research of the acids obtained in these different ways is that they are quite identical with each other.

On Acetylbenzol.—M. Glaser.—Acetylbenzol, phenylacetylen, $C_6H_5.C_2H$. This body has been prepared by the author from phenyl-propiolic acid and styrol, and which has been obtained by MM. Berthelot and Friedel by other means, is possessed of the remarkable property of combining with metals and metallic oxides, some of which are treated of in this paper. The copper compound of acetylenbenzol, $(C_6H_5.C_2)_2Cu_2$. Diacetenylphenyl, $C_{16}H_{10}$, is a solid substance, soluble in boiling alcohol and insoluble in water; it is a peculiar hydrocarbon, obtained when acetenylbenzol copper is treated with a concentrated alcoholic solution of ammonia. Acetenylbenzol sodium, $C_6H_5.C_2Na$; this substance has only an ephemeral existence; it is instantaneously decomposed, both by moist and dry air.

Communications from the Chemical Society at Zurich, called the Chemical Harmonica.—M. Meister writes—"At the meeting held on the 27th of July last, MM. Merz and Weith spoke about acetanilide. In pure state, this substance is soluble in hot water, fuses at 113°, crystallises very readily, and is decomposed by sulphuric acid, acetic acid being set free and sulphate of aniline formed. In order to detect acettoluide among acetanilide, the acetic compound is dissolved in four parts of glacial acetic acid, and next mixed with about eighty parts of water; hereby the acetanilide remains dissolved, while the acettoluide is precipitated. MM. Baltzer and Merz obtained, by distilling a mixture of potassium-disulphonaphthalate and cyanide of potassium, a peculiar cyanide of high melting point, soluble in hot alcohol; this dicyannaphthaline is entirely acidified (*acidificirt*) by treating it with alcoholic solution of potassa, or by HCl at about 199°, while ammonia is at the same time generated.

Derivatives from Uramidobenzoic Acid.—M. Griess.—Uramidobenzoic acid, $C_8H_8N_2O_3$, is prepared by the action of a mineral acid upon a peculiar basic compound, $C_{30}H_{30}N_4O_9$, obtained by the action of cyanogen and an alcoholic solution of amidobenzoic acid. In this lengthy monograph, the author treats of several derivatives obtained from the uramidobenzoic acid by the action of nitric acid; among these new compounds, dinitro-uramidobenzoic acid, $C_8H_6N_4O_7$, is soluble in alcohol and ether, yielding, on evaporation, well-defined crystals. The paper is too concisely and abstrusely written to be fit for further condensation.

Illustration of the Phenomena of Combustion for Lecture Experiments.—Dr. A. W. Hofmann.—We greatly regret that, in consequence of the absolute necessity of the woodcut added to this paper, for it to be properly understood, we cannot abstract this communication of the eminent author.

Nature of Aniline Green.—MM. Hofmann and Girard.—We have already briefly noticed this memoir (see CHEMICAL NEWS, vol. xx., p. 153). This German paper is identical with the French one already alluded to.

On those Compounds of Essential Oil of Mustard which are Isomeric with Hydrosulphocyanic Acid.—Dr. A. W. Hofmann.—This is a fifth paper on this subject, not well suited for condensation with due regard to the labour bestowed upon the contents by the learned author.

Researches on the Products of Desulphuration of Diphenyl-sulphocarbamide.—Dr. A. W. Hofmann.—This memoir is too lengthy and too concisely written for any useful abstraction.

On some Superiodides.—M. Jörgensen.—This paper is an abstract of a larger memoir on this subject. The author treats of the superiodides generated when neutral or acid solutions of the hydrochlorates of morphia, codeia, papaverine, narceine, and narcotine are treated with solutions of iodine in iodide of potassium, in which case superiodides are formed which exhibit crystalline structure. Tetraiodide of morphia, $C_{17}H_{19}NO_3HI_4$, is precipitated in crystalline form when, to the aqueous solution of the salt of morphia, an excess of iodide of potassium is added. Teriodide of codeine and teriodide of papaverine, the former, $C_{18}H_{21}NO_3HI_2$, the latter, $C_{20}H_{21}NO_4HI_2$, have been found to contain hydriodic acid, since the alcoholic solutions, when shaken up with metallic mercury, yield double salts, only containing two equivalents of mercury. Sesquiiodide of narceine, $(C_{23}H_{29}NO_9)_2H_2I_3$, is formed when a very dilute solution of the hydrochlorate of the alkaloid is left standing for several weeks, after having been mixed with a dilute solution of superiodide of potassium. The author has extended his researches to piperine, atropine, berberine, theobromine, chinine, cinchonine, methylchinine, methylchinidine, ethylchinine, and ethyl-cinchonine; also to tetrethylphosphonium; but the great length and the large number of formulæ contained in this paper forbids us entering into more details on this subject.

This number of the periodical contains the queries to which answers are requested:—1st. By the Royal Prussian Academy of Sciences at Berlin; to be replied to before the 1st of March, 1870. The question proposed is the synthesis of either one or more such alkaloids as chinine, cinchonine, morphine, strychnine, brucine, or any non-nitrogenous compound so related to these bodies, that, by the action of ammonia, it can be converted into the aforesaid bases; prize, 100 ducats, about £50. For 1872, the same premium for a full investigation of the nitrogenous substances contained in wheaten flour and rye flour, and the changes these substances undergo when acted upon by water. 2nd. The Association for the Promotion of the Industry of Prussia asks—The preparation of an enamel on cast-iron, of variegated colours, to be unaffected by exposure to air, and to have proved effectual for at least one year; premium, 300 thalers (£45). For a suitable substitute for the use of arsenic acid in the manufacture of fuchsine (aniline red), provided the substitute be no more expensive and not poisonous or dangerous to deal with; a gold medal, or 1000 thalers (£150). For good replies to the subjoined questions, the same premium:—(1) A method whereby the quantity of aniline and toluidine contained in commercial aniline (*anilinöl*, literally aniline oil) can be accurately, readily, and speedily determined; (2) to determine the influence which the various mixtures of these two substances have in regard to the quantity of aniline obtained; (3) to estimate what weight will yield the largest quantity of crystallised pigment. These three particulars have each to be answered in order to satisfy for the premium. The last meeting of the Chemical Society of Berlin, was held on the 11th of October, this being the report of the meeting held on July 26th last.

Bulletin de la Société Chimique de Paris, September and October, 1869.

These two numbers have been published together, and contain the following original matter:—The *procès verbaux* of the meeting of this Society, held on the 2nd and 16th of July last, from which we learn that M. Personne described two new combinations of sulphuric and pyrogallic acids obtained by him. One of these, a conjugated disulphuric acid, exhibits needle-shaped crystals; its baryta salt is efflorescent. This compound is accompanied by a blue substance, a product of oxidation. In addition to these, there is formed a monosulphuric acid, a solid substance, crystallising in large crystals, which, on the addition of baryta, yields a beautiful purplish colour. The author has estimated the sulphuric acid in these compounds by burning them in a current of oxygen gas, and conducting the products of combustion into a solution of permanganate of potassa, and precipitating the sulphuric acid by means of baryta. M. Grimaux spoke on a new kind of nitriles, the oxygenated nitriles of the aromatic series. Salicylo-nitrile, C_7H_5NO, is obtained by the dehydratation of salicylamide by keeping it at a temperature of from 280° to 300°. The new product is a solid body, crystallising in yellow-coloured crystals, fusing at about 285°; almost insoluble in ether, alcohol, chloroform, sulphide of carbon; soluble in 200 parts of boiling oil of turpentine, soluble in aqueous and alcoholic solutions of caustic potassa, and, by fusion with that substance, is transformed into salicylic acid.

The following papers and memoirs were read:—

On a Homologue and Isomer of Choline.—M. Wurtz.—This paper is chiefly intended to point out the identity of neurine and choline, which last-named substance was originally found by M. Strecker in bile, while neurine, as discovered by the author of this paper, is artificially produced by the action of triethylamine upon hydrochlorate of glycol.

Action of Hydrochlorate of Glycol upon Toluidine.—M. Wurtz.—The author describes the action of hydrochlorate of glycol upon aniline and toluidine, exposing at great length the different reactions which take place, and the preparation of divers salts, especially with platinum as basis. The memoir is too lengthy to admit of useful abstraction.

Synthesis of Naphthalin-Carboxylic Acid.—M. Eghis.—This acid is obtained by acting with sodium amalgam upon a mixture of monobromated naphthalin and chloroxycarbonic ether. The acid so obtained appears to be identical with the menaphtoxylic acid of M. Hofmann, but differs from the carboxylic acid obtained by means of the cyanide of naphthyl prepared from sulpho-naphthylate of potassium by M. Merz.

Action of Anhydrous Sulphuric Acid upon Perchloride of Carbon.—M. Schutzenberger.—There is produced a liquid boiling at 130°, decomposed by water into sulphuric and hydrochloric acids, fuming in the air, and giving off a smell which is similar to that given off by some of the chlorides of the metalloids. The action of anhydrous sulphuric acid upon tetrachloride of carbon is represented by the following formula:—$S_2O_6 + CCl_4 = CCl_2O + S_2O_5Cl_2$.

Synthesis of Glucosides.—M. Schutzenberger.—The chief result obtained by the author is that the synthesis of genuine glucosides which agree in their properties with those formed naturally,

is possible by means of the double decomposition of the acetic glucoses (*glucoses acétiques*) and the lead or soda salts of several organic principles. The author is engaged in further researches on this subject.

Acetic Derivatives of the Sugars.—MM. Schutzenberger and Naudin.—This paper is too lengthy and too concisely written to admit of useful abstraction.

Inuline and its Acetic Derivatives.—MM. Ferrouillat and Savigny.—The authors have prepared inuline from dahlia root and from the root of the inula helenium. Notwithstanding that these substances have been carefully manipulated, so as to ensure the purity of the inuline, it appears that, from the experiments made, that this substance, as obtained from either of the two roots named, does not behave in the same manner when treated with acetic acid under exactly similar conditions, but yields products of decomposition which vary greatly. It is impossible to enter into details about these researches, since the paper is too lengthy for that purpose.

Oxidation of Pseudoctylic Alcohol.—M. Clermont.—The products obtained are the same as those yielded by castor-oil when it is oxidised.

Action of Permanganate of Potassa upon Cinchonine and the Existence of a New Alkaloid of the Cinchona Species.—MM. Caventon and Willm.—We have given an abstract of this from another publication.

Salts of Phenetosulphuric Acid.—MM. Opl and Lippman.—Phenetol is—

$$\left.\begin{matrix} C_6H_5 \\ C_2H_5 \end{matrix}\right\} O$$

It boils at about 169°. The authors describe a baryta salt of this substance, $(C_6H_4SO_6C_2H_5O)_2Ba'' + 4H_2O$, a phenetolsulphate of baryta, nearly insoluble in cold, but soluble in hot, water. Phenetosulphate of lead, crystallising in cauliflower-like masses, soluble in water. Phenetosulphate of potassium—

$$\left.\begin{matrix} C_6H_4SO_6K \\ C_2H_5 \end{matrix}\right\} O + H_2O$$

is obtained by decomposing the baryta salt by means of carbonate of potassa. The salt obtained is readily soluble in water, and crystallises in needle-shaped crystals.

Structure of Cubical Pyramidal Crystals.—M. Wyrouboff.—This paper is not suited for abstraction, being a strictly crystallographico-geometrical paper.

Cresotic and Salycilic Acids.—M. Vogt.—By means of a complicated process, commenced by acting upon chlorinated xylen with fuming sulphuric acid, an acid has been obtained which is soluble in hot water, insoluble in cold water; soluble, also, in alcohol and ether, and violet-coloured by salts of iron. This acid is composed, in 100 parts, of:—C, 63·1; H, 5·12; O, 31·78. When toluen was treated in the same manner, salicylic acid, $C_7H_6O_3$, was obtained.

Succinate and Benzoate of Isopropyl.—M. Da Silva.—We have already abstracted the contents of this memoir, which was also published in another periodical.

There is added to this number a loose sheet, bearing title—

Ecole Supérieure des Sciences Appliquées de Mulhouse (*Laboratoire de Chimie*).—From this programme, approved and signed by the Recteur de l'Académie de Strasbourg and other authorities, we learn that there exists at Mulhouse an excellently-arranged school for the education of those who are either to be the heads or future managers of industrial works of various kinds. There is attached to this school a large and well-fitted chemical laboratory, wherein every opportunity is given for practical working, and at a very moderate expense, considering that thirty hours a-week are devoted to chemistry alone. The regular course of this school extends over two years, after which period those who desire it are examined, and certificates are granted, which are considered as rigorous proof of real efficiency. This school is, in miniature, what the celebrated Ecole Centrale des Arts et des Manufactures at Paris is on a large scale. Both these schools were originally established by private enterprise, and have become highly and deservedly esteemed, and are therefore fully approved of by the authorities of the Université de France.

Polytechnisches Journal von Dingler, first number for September, 1869.

This number contains the following original papers relating to chemical science:—

Proper Mode of Applying Zinc-White as a Pigment.—Dr. Dingler.—The author disapproves of the use of any substances containing lead, or any preparations thereof, along with zinc-white. He recommends, instead of the use of ordinary boiled linseed oil, to mix the zinc-white with an oil prepared in the following manner:—200 lbs. of linseed oil are gently boiled, first, for some five or six hours alone, and, next, boiled again along with 24 lbs. of coarsely-broken-up peroxide of manganese for at least twelve hours; in this manner, a very quickly-drying linseed oil is obtained, which is eminently fit for the purpose of being used with zinc-white and other zinc colours. The author lays stress upon the use of old linseed oil, and also upon the care to be taken with the boiled oil, which unless carefully kept from access of air, becomes thick in a very short time. The boiled oil so prepared ought not to be used in painting with zinc-white by itself alone, but should be mixed, in quantities of from 3 to 5 per cent, with the raw linseed oil used to mix up the paint.

Optical Milk Test.—Dr. Heeren.—This is a lengthy essay on a subject of great importance. The author points out that chemical analysis only is the proper mode of testing the quantity of butter contained in milk; but he also observes that this requires more knowledge, and also more time than those practically interested in this subject can devote to it. The author then reviews a variety of instruments devised for the purpose of testing milk; among these, M. Chevalier's crämometer is noticed. In the first place, the awkwardness of this instrument is due to the fact that the milk has to stand therein for at least twenty-four hours; and, although for milk intended for butter-making this is no objection, it is not desirable for daily use. The optical milk-testing apparatus devised by M. Donné, in the year 1843, and M. Vogel, in 1862, are described, and their value reviewed. The general results obtained by this author may be recapitulated as follows:—Skimmed milk contains fat globules of smaller size than unskimmed milk; smaller globules produce a relatively greater turbidity than larger-sized globules. Since the value of the optical milk-test is based upon the degree of non-transparency, it cannot yield correct results for wholly or partly skimmed milk. Carefully-made experiments prove that the use of M. Vogel's galactoscope gives perfectly correct results, but only for pure and unskimmed milk. By means of a combined optico-chemical investigation, it is possible to detect the precise quantity of fatty matter withdrawn from milk. The increase of the specific gravity of milk by skimming it is in direct proportion to the quantity of fatty matter withdrawn.

Quantitative Analysis of Soap.—M. Span.—Too lengthy to admit of useful abstraction.

Crystalline Coloured Substance Prepared from Mica.—Dr. Tech.—This paper contains the results of researches made with the view to detect the colours applied to minute pieces of mica used for ornamental purposes under the name of *brocate*. The following colours were tested:—*Rose red.*—Proved to be cochineal. *Carmine red.*—The colour is soluble in hot water; ammonia destroys the colour, HCl makes it yellow; colour is soluble in spirits of wine; the colour of that solution is destroyed by ammonia; colouring matter is, therefore, fuchsine. *Violet.*—Hardly soluble in water; completely soluble in water acidified with acetic acid; discoloured by ammonia; turns first green, and then yellow, by addition of hydrochloric acid. *Bright blue.*—Insoluble in water and water acidified with acetic acid; insoluble in alcohol; soluble in aqueous solution of oxalic acid; discoloured by alkalies. *Berlin blue.*—Deep blue; as far as tests could prove, this appeared to be Girard's violet, green, a mixture of aniline blue, and turmeric. Violet blue was evidently obtained with log-wood, and this was also applied to black.

Non-Porous Copper Castings may, according to the editor, be obtained by melting copper in plumbago crucibles previously lined inside with pipe-clay and dried. As soon as copper, while in molten state, is in contact with coal or carbonaceous matter, it yields a porous and spongy casting.

Pharmaceutische Zeitschrift für Russland, August, 1869.

This number contains the following original papers:—

Contributions to a Monograph on Inuline.—M. Dragendorff.—This paper is the first instalment of a memoir on inuline; it contains—(1) an historical introduction; (2) an essay on the different species of plants and parts of plants in which inuline is found; to these belong *Inula Helenium, L., Taraxacum officinale, Cichorium Intybus, Anacyclus officinarum, Helianthus tuberosus.* Inuline (also known as *helenin, alantin, dahlin, menyanthin*) is chiefly contained in the roots of the plants alluded to; it is a substance isomeric with, and in its properties similar to, starch, and was discovered in 1804 by M. V. Rose; its formula is $C_6H_{10}O_5$. The paper on this subject is to be continued.

Comparative Essay on the Characteristic Properties of the Halogens and their Combinations, and particularly on Hyperiodic Acid.—M. Ferrein.—This is the last instalment of a very lengthy essay on this subject.

Method for Rapidly Separating the Nitrates of Silver and Copper from each other.—Dr. Palment.—The author had to prepare nitrate of silver from small silver coins which contained a large percentage of copper. The alloy is dissolved in nitric acid; the solution is filtered if necessary, and evaporated until it has the consistency of a thickish oil; when this point is reached there is added to the solution very concentrated nitric acid free from HCl. By this proceeding all the nitrate of silver is precipitated, while nitrate of copper remains in solution. One part of the concentrated metallic solution requires from three to four parts of nitric acid for the complete precipitation of the nitrate of silver; the more concentrated the nitric acid is so much the better, but acid of 1·250 sp. gr. answers the purpose. The solution of copper is decanted off, and the nitrate of silver washed with nitric acid.

Researches on the Excrements of the Silkworms.—Dr. Palment.—These excrements contain 13·33 per cent ash, composed of potassa, soda, a trace of magnesia, carbonic, sulphuric, phosphoric acids, and chlorine. Among the organic substances contained in these excrements, the author found starch, mucus, sugar, tannin, and a peculiar green pigment. The worms had been fed only on the leaves of the white mulberry tree.

On Jantak-Schakar.—Dr. Palment.—Under this name there is sold in the towns of Central Asia a yellowish-coloured, dirty, hygroscopic substance, which is used as sugar, but the author has not been able to learn how it is obtained and from what plant it is derived; he found it did not contain mannite, and yielded on analysis, in 200 parts:—Sugar, 56; water, 11·4; impurities, 21·7; the latter being partly woody fibre, and partly inorganic salts.

Researches on a Petroleum from the Kirgisensteppe.—M. Both.—This oil occurs in wells at a considerable distance from

Orenburg; its colour is brownish-black, its consistency like tar; specific gravity, at 14°, 0·87; it contains 17 per cent of water, wherein 0·80 per cent of sulphate of protoxide of iron, readily soluble in ether, alcohol, benzol, chloroform, oil of turpentine, and miscible in every proportion with fatty oils; boiling point, 380°. This oil is purified with great difficulty; it contains 1·87 per cent of sulphur.

Les Mondes, October 7, 1869.

This number contains the following original communications:—

On the Radiant Heat from the Moon.—M. Marié-Davy.—The author says:—I do *not* admit that there is any essential difference between light and heat; I do not say that the *vis viva* of the moon's rays is *nil*, but I say it is so infinitesimally small that it is incapable of raising the temperature of an air-thermometer upon which the moon's rays concentrated by a strong lens were directed 0·0004°; and the heat radiated is not sufficient to raise the temperature 0·000001° when the bulb of the thermometer is directly exposed to the moon's rays. Suppose we apply either a lens ten times stronger than the one we employed, or a thermometer ten times more sensitive, and we thereby magnify the effects of course so that a motion of 1 m.m. will take place which will be very perceptible. If my observations were contradicted by those made by the late Lord Rosse, that nobleman ought to have drawn from his observations the conclusion that the direct rays of the moon were capable of elevating the temperature of a thin blackened object 0·000001°. The sun's rays increase about 12° the temperature of a thermometer placed in an apparatus invented by the Rev. Father Secchi, S. J., the obvious result of my observation alluded to above would lead to the result that the *vis viva* of the sun's rays is 12,000.000 times larger than those of the moon's rays. The moon by no means reflects the total quantity of rays which she receives, and since, in all probability, its radiation is diffuse, it follows that its rays when arriving upon our planet are weakened in the ratio of the square of the diameter of the moon's orbit and of the diameter of the moon itself. The moon's rays are not necessarily of the same composition as those of the sun, and it is a well-known fact that the calorific power is not proportionate to the illuminating power in the sun's spectrum. A common argand lamp placed at a distance of two metres from my experimental thermometer by the heat radiated from it caused the mercury to move through more than 1 m.m. of space, while the moon's image, though giving far more light, did not cause the mercury to move at all.

Naphtha as Fuel for Locomotive Engines.—M. Portski.—This Russian engineer has run a railway train successfully for a distance of 81 versts* from Charff to Kutschigan, the only fuel applied being raw commercial naphtha, instead of coal, coke, or wood.

The Journal of the Franklin Institute, August, 1869.

This number contains the following original papers and communications:—

Old and New Coal.—Dr. Morton.—The author says:—Attention has been lately drawn to a curious observation, which is given as a fact without sufficient explanation. In one case, where hard coal is used in large quantities for purposes of mere evaporation, it appears that some which has been kept on hand in open piles for five or six months is less effective by from 13 to 15 per cent than that fresh from the pit. The deterioration caused by the absorption of water is, of course, well known, but does not seem to apply to these cases. The fact here alluded to is very well known in this country (England), and also elsewhere on the European continent, but is not quite scientifically explained.

The New Chemical Nomenclature.—Dr. Ott.—This is the first portion of a lengthy paper which the author intends to publish on this subject. He says—"The deficiency of the present system of chemical nomenclature, though immensely felt for many years, has been chiefly brought to light by the astonishing strides of organic chemistry." The author points out the great inconvenience of a nomenclature containing names with seventeen or more syllables; though, in a less distinct manner, this deficiency is also felt in the domain of inorganic chemistry. We meet here such scarcely pronounceable denominations, as "hypersulpho-molybdate of potassa," "sesquibasico-ammoniaco-sulpharseniate of soda," and many others. The author proceeds to point out that the history of the spoken language of chemistry shows more clearly than that of any other science its various conditions in the succeeding stages of progress. The early cultivators of science hid their doctrines under the veil of an obscure figurative language, adopting at the same time particular characters for signifying bodies known to them. In the belief that the celestial bodies exercised a direct influence on terrestrial products, they consecrated the metallic and other substances to the seven so-called planets. As instances, we mention that to Saturn were consecrated the lead, litharge, and agate; to Jupiter, tin, corals, all white stones, and sulphur; to Mars, the iron, loadstone, and pyrites, and so on. Traces of this nomenclature yet remain in such terms as *Arbor Dianæ*, tincture of Mars, Martial pyrites, and lunar caustic. The term *sal* has been used since the oldest times for everything tasting like salt, or even for such substances as carbonate of potassa, which share only some properties with the same—viz., solubility in water, deliquescence, and colour. As instances of figurative expressions, we meet with *aqua ardens*, for alcohol, *lapis aquilinis*, &c. The author proceeds in this manner, passing in review the history of chemistry, but what has been quoted sufficiently exhibits the wide range he has taken for the full treatment of an interesting subject.

Camphoric Acid and some of its Combinations.—M. Fairthorne.—By repeated distillation of camphor with nitric acid, that substance is converted into camphoric acid by absorption of six equivalents of oxygen. The composition of camphor being $C_{20}H_{16}O_2$, that of camphoric acid is $C_{20}H_{14}O_6+2HO$. It (the acid) dissolves freely in alcohol and ether, moderately in water, but is insoluble in benzol and chloroform. It combines readily with ammonia and other alkalies; the ammonia salt crystallises in silky, star-like crystals. Its aqueous solution behaves, with the substances hereafter named, in the following manner:—With perchloride of iron, a light brown precipitate; no precipitate with the proto salts of iron; with sulphate of copper, a bright green precipitate; with solutions of salts of lead and mercury, dense white precipitates; no precipitation with sulphate of zinc, sulphate of morphia, sulphate of quinine, sulphate of cinchonia, sulphate of magnesia; none, also, with lime-water or soluble salts of silver. The author proposes to use the peculiarly bright green coloured precipitate yielded with sulphate of copper as a test for copper, since even 1 grain of sulphate of copper in a pint of water yields a distinctly perceptible colouration.

Cosmos, October 9, 1869.

Test for Berlin Blue.—The late M. Nicklès.—Shortly before his death, this *savant* pointed out that, when woven fabrics dyed with Berlin blue are steeped in a solution of fluoride of potassium, and then submitted to the action of steam, the colour of the tissue is at once discharged. Fabrics dyed with indigo or with aniline blue, when submitted to the same treatment, remain unchanged.

Drying of Wood.—For this purpose, the wood is kept for some hours under boiling water, whereby all its soluble parts are withdrawn. It is next left to dry, and then boiled for some time in a solution of borax, which causes the albumen to become soluble, and to escape from the pores. After this proceeding, the wood is placed in stoves heated by steam, and, in three days after the commencment of this series of operations, it has become quite dry and thoroughly seasoned.

NOTES AND QUERIES.

Magnesium Lamps.—(Reply to "C. Hunter.")—Messrs. Johnson and Matthey, of Hatton Garden, can give information about, and probably supply, every kind of magnesium lamp.

Magnesium Lamps.—(Reply to "C. Hunter.")—Larkin's magnesium powder lamp may be obtained of Mottershead and Co., Manchester.

Halliday's Machines.—Can any of your readers inform me where to find the makers of "Halliday's machines" for treating sawdust in the manufacture of pyroligneous acid and acetate of lime, and also the makers of the best wood-distilling apparatus.—A. W. N.

Carbonic Acid.—(Reply to CO_2).—Why not rather make carbonic acid by Ozouf's process, that is, by forcing air through previously strongly-ignited charcoal, contained in a properly constructed stove or furnace? It is true the gas thus obtained is contaminated with carbonic oxide and a very small quantity of combustible gases. The process alluded to by you is patented, I think, but it is certainly not a cheap process, and, if your limestone is tolerably pure, you had better dissolve it in either hydrochloric or sulphuric acids (both diluted with water, of course), and collect the gas thus set free.—J. A.

TO CORRESPONDENTS.

A Trustee.—It will be necessary for you to send your name and address before we insert your query respecting the Andersonian Institution.

E. N.—Apply to Messrs. Baillière, Regent Street, for the foreign journals you require.

F. Cox.—You will find information on the Uranium Process for Estimating Phosphoric Acid in Nos. 430 and 432.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give Instruction in all branches of PRACTICAL CHEMISTRY, particularly in its Application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from Ten to Five o'clock; on Saturday from Ten till One o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses apply to Mr. Henry Matthews, the Laboratory, 60, Gower-street Bedford Square, W.C.

* There are in use two kinds of measures called versts in Russia, which differ rather considerably in value, but one of these measures is only used in the Baltic Provinces of Russia; the verst more generally in use has a value of 1066·78 metres, the English statute mile being equal to 1609·315 metres; 81 versts is therefore equal to 53·6 English miles.

THE CHEMICAL NEWS.

VOL. XX. No. 518.

THE CHEMISTRY OF THE BLAST FURNACE, ACCORDING TO MR. I. L. BELL'S EXPERIMENTS.*

By M. CHARLES SCHINZ.

MR. I. LOWTHIAN BELL has lately read before the Chemical Society a paper on "The Chemistry of the Blast Furnace," this paper which is published in the Journal of the Society for June last, containing an account of a series of experiments which he has made on the process of the reduction of the iron ores in the blast furnace, and by means of which he intends to prove that this reduction takes place at a temperature much lower than that previously found by Scheerer, Ebelmen, and Tunner.

Mr. Bell comments at first upon the irregularity with which the layers in the blast furnace come down, and judges from that, that the volume of the blast furnace cannot be divided precisely into "zones." It should be stated, with regard to this, that it is absolutely wrong to charge a furnace with pieces varying much in size, this variation, of course, producing an unequal reduction and an irregular descent of the layers. But if this mistake is often made in England, it does not follow that the temperature in the blast furnace, with careful charging, should not decrease in an uniform and constant manner, so that it may really be divided into zones, limited by fixed temperatures: a difference of temperature is not even a necessary consequence of charging the furnace with pieces of unequal sizes, as the hot gases give up the heat with equal rapidity to large and small pieces, because this transfer depends simply upon the heat-conducting power of the materials. If, however, the free space between the pieces of the charge is not the same on both sides, the gases will rise much quicker on one side than on the other.

Of course small pieces of ore are more quickly and more completely reduced than larger ones, but large pieces, as well as small pieces, will be acted upon according to the existing temperature by the rising carbonic oxide; while, if they descend to such a depth of the furnace that the slag begins to run, the reduction ceases entirely, and afterwards it can only be accomplished, at a still higher temperature, out of the slag which contains oxide of iron by means of solid carbon. But that cannot influence the action of a zone of reduction, for the reduction by means of solid carbon is a different action, including other phenomena, and has to be examined separately.

If now the experimenters above named fixed the limits of their zones at very different heights of the shaft of the furnace, they have either erroneously taken the depth of the furnace as the extreme limit, whilst the volume of the zones ought to have been decided, or but very uncertain means of determining the temperature must have been at their command.

Mr. Bell has, on the other hand, put the ores to be reduced for a greater or less time into the iron pipes by which the gases are led from the furnace, and, moreover, into the pipes of furnaces of different size which, of course, give off gases of different temperatures; and, as he has thus found that a reduction takes place even at the melting point of bismuth (257° C.), he argues consequently that all that has been formerly stated about the temperature necessary for the reduction must be wrong. If Mr. Bell has really measured his temperature in a correct manner, of course then he is entitled to this conclusion; but it is a question whether Mr. Bell's measurement of the temperature does not depend upon a delusion. All compact metals possess a much greater heat-conducting power than the ores. If we put upon the bottom of a gas-pipe pieces of ores and a piece of metal, the latter will not melt, for the atmospheric air cools the tube from below, and deprives the piece of metal which is in contact with the tube of the heat necessary for the melting, whilst the pieces of ores, with less conducting power, are exposed to a perceptible higher temperature.

If we suppose that the temperature of the pieces of ore was the same as that of the piece of metal which served for ascertaining the temperature, the conclusion at which Mr. Bell arrived is still only delusively correct, for the conditions of the chosen method of operating are different to those existing in the blast furnace. The quantity of gas passing through in proportion to the mass of ores is much larger in the pipe leading off the gas than in the shaft of the furnace itself. My own experiments (see *Documente Betreffende den Hokofen*) have proved that the reduction is as much accelerated by the proportionate quantity of gas as by the amount of carbonic oxide which these gases contain, and that the intensity of the reduction, therefore, depends together upon temperature, quantity, and abundance of CO, and that no comparable results can be obtained without taking into consideration, and without determining, all these three factors. The influence of the composition of the gases upon the process of reduction has been presumed by Mr. Bell, and he has therefore, made special experiments with gases of the furnaces at Wrbna and at Clarence.

These gases have, according to Mr. Bell, the composition:—

13 CO + H, 16 CO_2, 71 N (Wrbna), and
32 CO + H, 6 CO_2, 62 N (Clarence).

But such a composition of blast furnace gases is almost impossible, for these gases must contain, if no direct reduction by means of solid carbon takes place, for 100 equivalent of nitrogen, 26·6 equivalent of vapourised carbon, and 26·6 equivalent of oxygen, plus the oxygen added by the reduction of the ores.

Now, the gases of the Wrbna furnace contain:—

13 CO and 16 CO_2
6·5 ,, 16 = 22·50 O
for 100 N = 31·69 O;

the surplus of oxygen from the ores would thus be only—

$$31{\cdot}69 - 26{\cdot}51 = 5{\cdot}18;$$

well, but whence came the 16 CO_2?

Besides 13 CO and 16 CO_2 contain
6·5 ,, 8 vols. = 14·5 C.,

which gives 20·42 carbon instead of 26·51 for 100 N.

The result of Tunner's analysis is, therefore, decidedly wrong.

The composition given for the gases of the Clarence furnace, namely:—

32 CO, 6 CO_2, 62 N,

is just as false.

These gases contain 22 volumes of O for 62 N, and this for 100 N = 35·48 O; next, also, they have 19 carbon for 62 N, or for 100 N there would be 30·64 carbon. The surplus of O thus equals 8·88 per cent, and of C = 4·04 per cent.

The gases of Clarence Iron Works should have, according to Mr. Bell's own calculation, the composition—

Cold Blast.

Weight of carbon	32·79	= volume	30·48
,, ,, oxygen	50·22	,,	35·11
,, ,, nitrogen	142·60	,,	113·48

per 100 N = 26·86 C.
30·94 O.

* *Engineering*, October 22, 1869.

The surplus balsam around the edges of the cover will require to be cleaned off; but this must not be attempted until it has become hard and firm. The hardening of the balsam may be much accelerated by the application of heat. The inside of a fender is a very convenient place for drying balsam-mounted slides. A drying apparatus for effecting this more quickly is described by Mr. D. E. Goddard, in the *Transactions of the Microscopical Society of London*, January, 1864, p. 45.

The simplest way of removing the surplus balsam is to make it very hard, and then wet the slide, and scrape away the balsam with a wet knife. It comes off very readily, and leaves the slide so clean that it can be easily finished with a rag and a little methylated spirit. Where the balsam is not very hard, it is better to scrape away as much as possible with a hot knife, and remove the remainder with alcohol, being very careful not to disturb the cover. The knife for scraping the slide should be softened by heating to redness and allowing it to cool, or it will scratch the glass.

The forceps and needles may be cleaned from balsam by heating in a spirit-lamp, and wiping with rag or blotting-paper. The forceps should be common brass ones, as steel would soon be spoiled, and the needles kept for this particular purpose, as they are useless for any other. Balsam may be removed from the fingers by a free use of methylated spirit.

Canada balsam is best preserved for use in the collapsible tin-tubes used for containing oil-colours. As already mentioned, air is largely absorbed by balsam; indeed, most varnishes dry quite as much by the absorption of oxygen as by evaporation. The advantage of the tube as a receptacle is that the balsam is kept quite close to the top of the tube, and no air allowed to remain there, so the balsam may be preserved in a perfectly fluid state for a long period. Balsam has been kept for two years in these tubes, and been as limpid as when the tube was filled; while, in bottles, the balsam rapidly hardens, and becomes useless if long kept. The tubes have also the advantage of cleanliness in use: the supply is obtained by squeezing out the quantity required, the use of a dipper, an endless source of dirt and introduction of foreign substances, being dispensed with. Should a little balsam ooze out around the screw-cap, it can be scraped away with a hot knife. These tubes also form convenient receptacles for varnishes which are liable to injury by being exposed to the air—such as gold-size. They do not answer for varnishes made with naphtha or spirit, as these varnishes dry entirely by evaporation, and soon fasten down the cap.

Solutions of balsam in various media have been much used by some microscopists. They have the advantage of allowing the mounting of an object to be effected without the employment of heat, a great desideratum in many cases. Chloroform has been the medium hitherto employed for dissolving the balsam, which is previously exposed to a slow heat, until it is dried into a hard, resinous mass. It has been found, however, that objects mounted in this solution have frequently become cloudy, and that the solution, if kept for a considerable period, becomes turbid. Dr. Bastian recommends the use of benzole as a solvent, on the ground of its greater stability. He has made great use of the solution as a medium for making preparations of nervous tissue. A detailed account of his processes will be found in the *Monthly Microscopical Journal*, vol. i., p. 94.

The solution of balsam and benzole is most conveniently kept in a wide-mouthed bottle, with a ground cap instead of a stopper, which will allow a small pipette to be kept in the bottle. Should the fluid become too thick from evaporation, a little more benzole may be added.

Besides the use of balsam as a mounting medium, it is useful as a cement for a special set of purposes. The microscopist who makes the osseous tissues, rocks, or hard substances in general his particular study, will often require thin sections.

The preparation of a bone section will serve very well as an example of section-cutting, and polishing in general. It is required to make a very thin section of a recent bone, polished on both sides, to be mounted dry. The bone is to be cut into thin slices with a watch-spring saw. A level surface is then to be made on one side, by grinding down with water on a piece of blue-stone, or Water-of-Ayr. If the slice is very rough, time may be saved by using a file in the first instance, and finishing on the stone. The fingers may be protected from the action of the stone by bedding the rough section in a piece of cork.

The bone slices are to be cemented with Canada balsam, by their ground sides, to pieces of thick plate-glass; 1¼ inches by ¾ of an inch is a convenient size for general use. The chief art consists in using the balsam of the right degree of hardness. A drop of balsam is to be placed on one of the slips, boiled on the hot plate, and allowed to cool. If, when cold, it is just capable of receiving a slight impression of the thumb-nail when pressed hard, it will do. If too soft, it must be heated again, and allowed to cool, and the process repeated, if necessary, until the right degree is obtained. If the balsam is not hardened sufficiently, it will clog the stone in the subsequent process; and, if too hard, it is liable to chip off along with the partially-finished section during the grinding. The piece of bone, cemented in its balsam bed, is to be ground down with water until the surface is levelled. It is then to be polished, so that no scratches appear upon it when examined under the microscope. This is done with putty-powder (oxide of tin, and not in any way connected with glaziers' putty), used with water upon a wash-leather strop. When the polishing is completed, the section is to be removed from the glass, which can be done by dropping it into a bottle of benzole, which will dissolve the hardened balsam, and release the section in a few minutes. A wide-mouthed stoppered bottle is convenient for this purpose, and the pieces of plate-glass are cut of the small size recommended, in order that they may be easily placed in and removed from the bottle. The half-finished section is now to be cemented to another balsam-bed, and ground down until it is sufficiently thin. With practice, 1-500th of an inch may be attained with a tough substance like bone. The author has approached this thickness even with fossil ganoid scales from the Weald clay. At first, it is well not to attempt too thin a section, and to practise on some material of which a large supply can be obtained. When ground sufficiently thin, the second surface is to be polished, and then detached as before, and afterwards washed in clean benzole, to remove all traces of balsam. The finished sections, when the benzole has dried off, are to be mounted dry by one of the usual processes.

Sections to be mounted in balsam will not require to be polished, as the balsam fills up, and, by its refractive power, apparently obliterates the scratches left by the grindstone. Other hard substances are treated in a nearly similar manner. Fossil bones and teeth, from their extreme brittleness, will require greater care in grinding, and, from their dark colour, must often be mounted in balsam, instead of dry. This is also necessary when they have a tendency to disintegrate. For very hard substances, such as teeth, the Arkansas stone would be of great service; but, unfortunately, it does not cut well when used with water, and, if oil is employed, the balsam is softened. A process devised by Dr. Christopher Johnstone about ten years ago, and published in *Silliman's Journal*, gives a process by which an oil-stone can be employed. The cement used is isinglass jelly, made with alcohol. Use is made of thin paper, as a guard against grinding away the section—an accident of frequent occurrence with beginners. The grinding is performed upon an Arkansas stone, with oil, and hot water is used to detach the section. The grease can be extracted with benzole. A detailed account of the process is given in the *Journal of the Quekett Microscopical Club*, 1869, p. 201. Accounts of the mode of cutting rock-sections, by J. B. Jordan, will be found in the same journal, p. 186, and, by D. Forbes, F.R.S, in the *Monthly Microscopical Journal*, vol. i., p. 240. The process of cutting sections of still harder substances, such as gems, is described by Mr, H. C. Sorby in the *Monthly Microscopical Journal*, vol. i., p. 220. Grindstones and polishing powders of various kinds can be obtained at the better class of tool shops, as Holtzapffel's, Buck's, Fenn's, &c.

Although it is the usual custom to cover slides containing dry and balsam mounted objects with paper, it is preferable to leave them without. A balsam-mounted preparation, well cleaned, and mounted on a piece of good patent plate with polished edges, is far neater than when covered with paper, which too often only serves to conceal an inferior quality of glass.

(To be continued).

PROCEEDINGS OF SOCIETIES.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

Ordinary Meeting, October 5, 1869.

E. W. BINNEY, F.R.S., F.G.S., Vice-President, in the Chair.

"*On Nontronite*," by T. E. THORPE, Ph.D., communicated by Professor H. E. Roscoe, F.R.S., &c.

There exists some doubt among mineralogists as to whether nontronite is to be regarded as a distinct mineral species. Owing to the difficulty of obtaining it in a fit state for investigation, the few analyses hitherto published by Berthier, Dufrénoy, Jacquelin, and others, have taught us but little concerning its real nature. The following analysis, made on a comparatively pure specimen, may throw additional light on the constitution of this compound. The sample analysed was discovered, unclassified, in the Mineralogical Cabinet at Heidelberg, and was stated by Professor Blum, who was disposed to regard it as pinguite, to have been found in the neighbourhood of Heppenheim, in the Bergstrasse.

1·4155 grms. of the substance was heated with fuming hydrochloric acid until the mineral appeared to be completely decomposed. The solution was evaporated to complete dryness, and the separation of the silica effected in the usual manner.

Silica obtained, 0·5680 grms.

The weighed silica was then dissolved in caustic potash, and proved to be entirely free from sand or quartz.

To the filtrate from the silica were added a few drops of nitric acid, the solution boiled, and the iron precipitated by ammonia.

Ferric oxide, 0·5757 grm.

The weighed precipitate was next dissolved in strong hydrochloric acid, water added, and the solution filtered from a minute quantity of silica which had escaped separation by the previous evaporation.

Silica (not completely separated), 0·0030 grm.

Caustic soda was then added in slight excess to the filtrate, and the ferric oxide again precipitated, washed, ignited, and weighed. The re-precipitated ferric oxide weighed 0·5740 grm. Hence the substance was free from any appreciable quantity of alumina.

To the ammoniacal filtrate a few drops of ammonium oxalate were added, and the precipitate ignited, and determined as caustic lime.

Lime, 0·0380 grm.

On adding sodium phosphate to the filtrate, a mere trace of magnesia, appearing only after the lapse of some hours, was found.

The remaining constituent (namely, water) was determined by igniting the mineral in a stream of dry carbonic acid, carefully freed from air, until the loss of weight appeared constant.

1·1205 grms. substance lost 0·2311 grm. water.

Calculated from the foregoing analysis, the composition of the mineral is as follows:—

Lime	2·68
Magnesia	traces
Ferric oxide	36·44
Silica	40·30
Water	20·98
	100·40

On subtracting the lime, which evidently may be regarded as an unessential constituent, the percentage composition agrees very well with that required by the formula $Fe_2O_3 3SiO_2 + 5H_2O$.

	Found.	Calculated.
Ferric oxide ..	37·24	37·20
Silica	41·29	41·86
Water	21·47	20·94
	100·00	100·00

Nontronite is evidently a product of the decomposition by weathering of some siliceous mineral rich in iron. It possesses a light green colour, which, on the expulsion of water, changes to a dark chesnut-brown. It is perfectly opaque, and shows no evidence of crystallisation. Its fracture is uneven, and the lustre of its streak resinous. It is unctuous to the touch, and yields easily to the nail, and is somewhat harder than talc.

The following analysis by Biewend, made upon a specimen found at Andreasberg, agrees remarkably well with the foregoing determinations:—

Ferric oxide	37·30
Silica	41·10
Water	21·56
	99·96

Dr. SCHUNCK, F.R.S., called attention to a paper by Vogelsang and Geissler, on the nature of the liquids enclosed in certain minerals, such as rock crystal, topaz, and quartz, which appeared in the number of *Poggendorff's*

Annalen for last May. The authors find that these liquids (supposed by some observers to be hydrocarbons) always consist of liquid carbonic acid, mixed, in some cases, with a little water. The experiments by which they were led to this conclusion are fully described in the paper.

NOTICES OF BOOKS.

Elements of Chemistry: Theoretical and Practical. By William Allen Miller, M.D., LL.D., &c. Part III. *Organic Chemistry.* Fourth edition, with additions. Longmans. 1869. 976 pp.

Dr. Miller's works on chemistry have become so thoroughly classical in chemical literature, that, at first sight, it may appear almost unnecessary to notice a new edition of one of them; it will be well, however, as the work has been revised and a good deal augmented, to point out the more important changes and afterwards to give a brief account of the general arrangement and classification of the subject matter.

The principal changes in this edition consist in the uniform adoption of the new notation, together with the system of nomenclature first introduced by Berzelius, then abandoned, and now revived by Wurtz and Cannizzaro, and generally adopted in the chemical world. The metrical system of weights and measures and the centigrade thermometric scale have also, in this edition, been placed side by side with our own scales and measures.

The entire work is divided into fourteen chapters, which gives an average of about sixty-eight pages to each chapter, and there is a further sub-division of each chapter into "parts" and numbered paragraphs. The first and introductory chapter treats of "Organic Analysis, Classification of Organic Bodies, Metamorphosis, Synthesis." Now it has been a good deal contested whether we should not abolish the term "Organic Chemistry," since the old distinction has fallen to the ground, and more than a thousand substances once believed to be formed and capable of formation only in the organisms of plants and animals, have been synthetically prepared in the laboratory of the chemist. Hence, at the outset of this work, we find a statement of the difference between *organic compounds* and *organised bodies*, the former of which can, in many instances, be prepared synthetically, while the latter are "the result of the action of living bodies upon inanimate matter," and cannot be prepared synthetically. Sugar, oxalic acid, and urea belong to the class of "organic compounds," while muscular tissue and ligneous fibre belong to the class of "organised bodies." As to the line of demarcation between inorganic and organic products, this does not exist, still, as Dr. Miller observes, "it is convenient to sub-divide chemical compounds into organic and inorganic; since those derived from the inorganic world, from the greater simplicity of their composition, afford to the student the most favourable instances for examining the fundamental laws of chemical combination, before he proceeds to the investigation of the more complicated products obtained from the operations of the living plant or animal."

The account of the analysis of organic bodies is followed by remarks on the classification of organic compounds, in the course of which the theory of compound radicles and of the Polyad Elements are discussed.

Chapter 2 treats of "The Saccharine or Amylaceous Group: Different Varieties of Fermentation," and is divided into four parts. The first is devoted to an account of the different kinds of sugar, and in it will be found (pp. 110 and 111) an extremely useful table giving a list of the various sugars, together with the principal properties and distinguishing characteristics of each. The table commences with cane sugar, and ends with pinite, $C_6H_{12}O_5$, which has been extracted by Berthelot from *Pinus Lambertiana*; it is a readily soluble substance, with a very sweet taste, not fermentable, incapable of producing mucic acid with nitric acid, and producing right-handed rotation of a ray of polarised light. Part 2 treats of the varieties of starch and gum, and contains an admirable statement of the theory of the action of ferments. Part 3, "Cellulin and Woody Fibre," includes an account of coal and other combustible materials, and useful tables of the analyses of coals. Part 4, "On Fermentation," treats of alcoholic, lactic, and viscous fermentation.

Chapter 3, "The Monatomic and Diatomic Alcohols and Ethers," is divided into seven parts, and extends over 120 pages. It commences with an account of the monatomic alcohols, passing to the ethers, and to the action of chlorine on ethers and alcohols. Part 5 treats of the "Metallic Derivatives of the Alcohols," commencing with zinc-ethyl; then kakodyle, AsC_2H_6, which was the first substance of this class, and was obtained by Bunsen; the name is unfortunate, especially if we are to call it kakodylide of kakodyle—$(AsC_2H_6)_2$ or Kd_2—; we certainly prefer the name *arseniodimethyl, or arsendimethyl*. There are hundreds of compounds in chemistry which might be called kakodyl with as much reason as arsendimethyl. The practice of naming a substance from one of many characteristics which it has in common with other substances cannot be too much reprobated or too soon abandoned.

Chapter 4 treats of the triatomic alcohols; "the Fats and Fixed Oils and Glycerine." Chapter 5 of the "Products of Oxidation of the Alcohols—Acids." The third part is devoted to the fatty acids, and the fourth to certain other vegetable acids, where will be found a detailed description of the modifications of tartaric acid, and mention of the remarkable series of acids obtained by Löwig by treating oxalic ether with sodium amalgam.

Chapter 6, "The Amides and Organic Bases," contains a very detailed account of the organic bases, commencing with the volatile bases which do not contain oxygen, and first of aniline. Among the natural bases we find the cinchona alkaloids, cinchonia, cinchonidine, and cinchonicine; the alkaloids of opium, of the peppers, of the *Strychnos* tribe, and, of tea, coffee, and chocolate. Chapter 7, "Of Essential Oils and Resins," contains Part 1 of Essences, 2 of Resins, 3 of Glucosides. Chapter 8 "Of Colouring Matters," contains a list of colouring matters obtained from lichens, and on page 665 we find an "Assay of Lichens for Colouring Matter." The most striking peculiarity of the lichen acids would appear to be their power of etherifying alcohol.

Chapter 9 contains an account of the "Products of Destructive Distillation." Chapter 10, "Compounds of Cyanogen; Bases of Animal Origin; Uric Acid and its Derivatives." The cyanides are divided into two classes—"Cyanides which do not contain Electro-negative Metallic Cyanides," among which are the zincic, plumbic, and palladious cyanides, and into "Cyanides which contain Electro-negative Metallic Cyanides," among which are the ferro- and ferri-cyanides, the nitroprussides, cobalticyanides and iridicyanides. Chapter 11, "Albumenoid and Gelatigenous Principles." Chapter 12, "Chemical Properties of some of the Solids and Fluids of Animal Origin;" and Chapter 13, "On the Nutrition of Plants and Animals." The two last chapters, which, together, extend over nearly 100 pages, will be of special use to medical students and those who devote themselves more particularly to physiological chemistry. Herein are discussed the chemical nature of—(1) the solid constituents of animals—bones, shells, horny matter, fibrous and elastic tissues, and of the components of the brain; (2) "Some Important Animal Fluids"—blood, chyle, lymph, milk, &c.; (3) the liquids concerned in digestion—saliva, gastric juice, bile, with a table of bile products; (4) excrementitious products—urine, excretin, and pus.

The fourteenth and final chapter is devoted to a discussion of "Atomic Volumes, and the Law of Boiling Points," and contains a number of useful and important tables. The first of these (pp. 941-944) shows the

density of a number of compound gases and vapours, and is arranged in the following order:—Name of compound, constituents, formulæ, density, calculated when H = 1 and when Air = 1, and observed in the latter case, and the authority. Next a table (p. 927) of the atomic volumes of elementary bodies; then the atomic volumes of certain oxides, sulphates, chromates, tungstates, carbonates, and nitrates, and of liquids of analogous composition. The remainder of the chapter is devoted to Kopp's law of boiling points. The fundamental proposition of this law is, as is well known, that for every addition of CH_2 in the empirical formula of compounds of ethyl and methyl, a rise of temperature of about 20° C. takes place in the boiling point; it has further been observed, as a general result of observation, "that the boiling point of a normal acid is 63° C. higher than that of its methylic ether, 44° C. higher than that of its ethylic ether, and 13° C. lower than that of its amylic ether; the boiling point of an alcohol of the form $C_nH_{2n+2}O$; is about 40° C. lower than that of its corresponding acid $C_nH_{2n}O_2$; a compound ether of the form $(C_nH_{2n+1}C_nH_{2n-1}O_2)$ boils at about 82° C. below the acid $(C_nH_{2n}O_2)$ which is isomeric with it." It is notorious, however, that very considerable discrepancies have been observed as regards the accuracy of Kopp's law, whether arising from inaccuracy of observation or from a defect in the law remains to be proved. Kopp has well observed in regard to these discrepancies "that it must not be assumed that the boiling points of liquids, when compared at *any* given pressure, will always exhibit the same differences as they do when compared at the average pressure of 30 inches (760 m.m.) of mercury. It does not follow, for instance, though the boiling point of ether is 79·5° below that of alcohol under a pressure of 30 inches, that under a pressure of 15 inches, the difference between these boiling points should still be 79·5°; since it is well known that what is called Dalton's law, viz., 'that all liquids at equal distances from their boiling point emit vapours of equal tension' is not correct."

The excellence of Dr. Miller's "Organic Chemistry" is so well recognised that it does not require one word of praise here. The very fact of its having reached a fourth edition (which is the fate of few large chemical works in this country), speaks for itself. Since Dr. Miller is constantly engaged in the teaching and the practice of chemistry, we are insured in his works the very newest matter, whether of theory or experiment. Thus we notice, in this edition, an account of the very recent researches of Messrs. Matthiessen and Wright on morphia and codeia. The constant reference to researches is of especial value, and if the year were more often added to the number of the volume and page of the work quoted, would be of still greater service. We regret to notice a somewhat large list of *errata* for a fourth edition, for although the corrections may be made once for all in ink, a work is always somewhat disfigured thereby. The use of a variety of types is now becoming more or less general in scientific works, especially on the continent, and when this can be done it certainly greatly facilitates reference; the broad thick letters and numbers are specially useful for the heads of paragraphs, while salts may be advantageously printed in small capitals, or with some other distinctive type characteristic: if in a later edition of the work we are considering this could be done, we think it could be consulted with greater readiness. We are almost surprised to find that Dr. Miller, whom we have been wont to account one of the more conservative chemists, has not only fully adopted the changes in the atomic weights and in the formulation of compounds, but has also introduced the changed names of substances, or, at least, one set of changed names. Thus it surprises us to find him speaking of "Plumbic Chloride," "Zincic Oxide," "Sodic Sulphate," and "Palladious Cyanide." The adoption of these terms by so eminent an authority will do much towards making them universal in the chemical literature of this country. We cannot help thinking sometimes, when we notice the extent and the variation of these changes, of the future of chemistry. If the science progresses in the next quarter of a century as much as it has in the last quarter (and there seems no reason to doubt that it will), there must of necessity be great and portentous changes. We cannot yet treat the facts of chemistry in a dogmatic and final manner. We cannot lay down such propositions as did Euclid of geometry; there is no absoluteness at present in our science; there is nothing of which we can speak with the same precision as we speak of the relation of the circumference of a circle to its diameter. And so long as this is the case some are of opinion that any changes tending to produce complexity should be avoided until their adoption has become, by the general consent of the chemical world both at home and abroad, a matter of absolute necessity.

CORRESPONDENCE.

BLOWPIPE CHEMISTRY.

To the Editor of the Chemical News.

SIR,—In my letter of the 17th of June, to your address, I state as follows:—"I reflected, however, that borax, being a compound salt, could scarcely be expected to give uniform results chemically, either as regards crystallisation or any other operation." The same reflection, together with a strong wish to obtain trustworthy reactions by the blowpipe through which the alkalies and alkaline earths could be detected, led me to try the colouration of Co solution with pure boracic acid, adding the alkali or earth to be experimented upon by traces at a time. I succeeded beyond my utmost expectation; the CoO, indeed, was scarcely at all dissolved in the pure BO_3; but I observed with my magnifying-glass spots of deep red-violet colour upon the cooler part of the platinum wire, which promised good results; and I found that, upon the addition of a trace of potash or soda, taken up on the hot bead, the CoO quickly dissolved, producing, in both cases, a pretty but light pink colour. I then generally (for I have made hundreds of experiments, with the detail of which I will not fatigue you) took upon the bead one more drop of Co solution, which deepened the pink colour, and showed a fine mauve-blue while hot. By the gradual addition of soda ($NaOCO_2$) to this, both the hot and cold beads were deepened in their tints, the former showing, for a moment, a deep blue-violet, and the latter remaining a splendid violet or purple colour. At last, the bead thus treated remains blue, both while hot and cold, and the amount of Na taken to effect this shows, I presume, pretty exactly that contained in borax.

The boracic acid cobaltine bead, treated in a similar way with potash, shows the same series of colours, but the potash blue is deeper, and has a dark violet tinge in it, which the soda blue has not, except when held against the flame of the lamp. On the addition of soda to a potash cobaltoboracic acid bead, this violet-blue is not changed, but even deepened; and the addition of potash to soda in a similar bead has a like effect. The addition of carbonate of lime to a boracic acid bead, with a drop of Co solution, produces a mauve-blue, opaque bead, magnesia a lavender-blue, opaque bead, both going through the gradations of pink, &c.

Fluor spar produces a clear bead; after a time, mauve-blue; so that the fluorine assists the boracic acid to dissolve the lime. Magnesia, assisted by a trace of potash or soda, may, by gradual addition, be made to go through the usual gradations of pink, &c., in a clear bead, until a mauve-blue is attained.

It will be proper here to detail two experiments showing the quantity of potash and soda taken respectively to satisfy an equal quantity of BO_3.

(1). "Measured very carefully half of 5 measures of BO_3, forming a bead about three-fourths the diameter of glass tube. Filled five measures with $NaOCO_2$; took a trace on hot bead, and added drop of Co solution; light pink, no undissolved Co discernible. Another drop Co solution; mauve hot, amethyst colour cold. Another trace Na; blue-mauve hot, dark purple cold. Trace more Na; lime-blue hot, blue-purple cold. Trace Na; deep mauve-blue hot, deep purple-blue cold. More Na; a little darker colours than before. More Na; mauve-blue. More Na; held against a bead of cobaltine borax, the blue still appeared mauve. More Na; not borax-blue yet. More Na; cobalt borax-blue. It took three-fourths of 5 measures (75 milligrammes); but, as it was a hydrated salt, containing, I should think, half its bulk in HO, I took half of this, or 35 milligrammes, to be the amount of $NaOCO_2$ taken to satisfy 50 milligrammes of boracic acid.

(2). Took half of 5 measures to form BO_3 bead, same size as last. Added drop Co solution and trace of $KOCO_2$ from 5 measures; pink, deeper than soda first trace. Added trace KO; light mauve hot, and light pink cold. Added drop Co solution; dark mauve hot, darkish purple cold. Trace KO; very dark blue hot, dark violet cold. Trace KO; dark mauve-blue hot and cold. Trace more KO; darker blue than last. Trace more KO; deep violet-blue, potash-blue. Took half of five measures (50 milligrammes), and, as it was also a hydrated salt, with less HO than the other, I estimated the quantity taken to satisfy the BO_3 as three-fourths of that, or 37·5 milligrammes; but I consider that too much, as I overdid the blue colour, and the KO was evidently more energetic in combination with BO_3 than Na, so that I should think it forms, with that acid, a triborate. I cannot procure caustic soda here, or would not have experimented with the carbonates of those alkalies.

(3). Filled five measures again, and took half to form a bead of BO_3, same size as before. (NB.—The loops of my platinum wires are all twisted of the same diameter). Filled five measures with $CaOCO_2$. Added trace Ca to boracic acid bead, with one drop Co solution; bead pinkish, with undissolved Co in spots. Trace Ca; opaque, lavender bead. Trace Ca; bead still opaque, of a blue-lavender colour, with spots of undissolved CoO, so added trace KO to clear it, and added trace BO_3 to make up for the KO; bead dark amethyst. Trace Ca; dark mauve hot, dark amethyst cool. Trace Ca; the mourning-violet colour cool. Trace Ca; deeper colour. Trace Ca; dark violet-blue, lime-blue. Took three-fourths of 5 measures (NB. This powder was extremely fine and dry, so that the above amount, 75 milligrammes, is, if anything, too little). I then made every effort, trying carbon, crystals of a solution of boracic acid in nitrate of cobalt, &c., to get the BO_3 to dissolve the CoO without the addition of an alkali, convinced, if I succeeded, I should get the beautiful wine-red or blood-coloured purple I had observed on the cool part of the platinum wire. I plunged the hot bead into cold water to cool it; I placed two small pieces of platinum wire in its centre for the same purpose, but without effect; and, as you will see from what follows, I found that BO_3 even acted as an alkali itself. Its energies are certainly feeble, and, even with a little KO, it failed to dissolve Cr_2O_3.

Reasoning analogically, I now concluded, as microcosmic salt gave a blue with Co solution not to be distinguished from that of borax, to attempt similar experiments to the above with pure or glacial phosphoric acid. I thought, at first, that I should have to make this myself, but was lucky enough to find two kinds in a chemist's shop here, who uses it in the preparation of some food. The kind which looked the purest, being like ice, I found, on being heated, gave off a smell of ammonia, and became so fluid as to drop off the platinum wire. I applied Co solution to what remained, and it immediately became blue—I presume, from the soda contained in the bones from which it was made. The other, in sticks like those of phosphorus, acted most energetically, and at once dissolved almost any quantity of CoO to a magnificent red-purple bead—the very colour I tried to get out of BO_3 and CoO in vain. On mixing BO_3 with this red-purple bead in considerable quantity, I obtained a blue, so deep that it appeared opaque, but, once seen, far surpassed in splendour of colour that of cobaltine borax.

I have not space or time to relate now my experiments with PO_5; but one fact is too important to omit, viz., that, with a slight trace of MnO_2 in the phosphoric bead, I obtained, by the persistent addition of soda, a rich brown colour, without any amethystine tinge, while potash gave, with the same oxide, an amethyst, with a far more purple tint than that of either the borax or microcosmic bead does with manganese.—I am, &c.,

W. A. Ross.

Simla, July 15th, 1869.

MISCELLANEOUS.

Glycoblastol.—Under this name there has been brought out at Vienna a cosmetic to be applied to the hair. It is simply made up of glycerine which has been digested with the rind of capsicum and perfumed with patchouli. As glycerine is by no means a proper substance to be applied to hair, this cosmetic, which is sold at an exorbitant price, ought not to be employed.

Fluid Glue.—To 1 kilo. of best glue dissolved, by the aid of a gentle heat, in 1 litre of water, 0·2 kilo. of nitric acid at 36° Beaumé (sp. gr. 1·334). After the at first rather strong evolution of nitrous acid vapours has ceased, the liquid is cooled and fit for use; a better product is obtained when dry clear glue (so-called gelatine) is treated and dissolved on a water-bath in its own weight of strong vinegar, one-fourth of its weight of alcohol, and a very small quantity of alum.

Elastic Glue.—Glue is dissolved in water by the aid of a water-bath, and evaporated until quite a thick fluid is obtained; to this a quantity of concentrated glycerine is added, equal in weight to the quantity of glue taken, and the evaporation is continued, while the mixture is frequently stirred, in order to drive off the remaining water; the mass is then run upon clean marble slabs, and cooled. This material is usefully applied for the inking-rollers of printers, and various other purposes.—*Deutsche Industrieblätter.*

CHEMICAL NOTICES FROM FOREIGN SOURCES.

In accordance with the generally expressed wishes of our friends and readers, we have effected arrangements to enable us to give, under the above heading, notices of EVERY CHEMICAL PAPER IN THE WORLD, *as soon as possible after publication. Whenever possible, these notices will appear in the form of carefully prepared, although necessarily brief, abstracts; as respects papers either too long or too abstruse to render condensation possible, their titles will be chronicled; and in all cases accurate reference will be made to the original publication. The two half-yearly volumes of the* CHEMICAL NEWS, *with their copious indices, will therefore be equivalent to an English edition of the "Jahresberichte," with the additional advantage of keeping the readers week by week on a level with the latest advances of science.*

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, October 18, 1869.

This number contains the following papers bearing upon chemistry and allied sciences:—

Metrical System: Critical Examination of the History of the Metre.—M. Chevreul.—From this lengthy paper we learn that, on the 14th of April, 1790, M. Brisson was the *savant* who proposed that a unit of measure should be taken from nature, by reading, at the Academy of Sciences, a paper "On the uniformity of measures of length, capacity, and weights, and on a new method of constructing the toise to be used as a standard." This paper of M. Brisson was written in consequence of the proposal made by the Bishop of Autun, as a member of the National Assembly, to render a uniform system of weights and measures compulsory by law throughout the entire French kingdom. The unit of measure of length proposed by M. Brisson was the length of the pendulum beating seconds at the latitude of Paris, which length had been very exactly determined by M. de Mairan, and found to be equal to 3 *pieds*, 0 *pouces*, 8 17-30ths *lignes*,

French measure. The Commission des Poids et Mesures, which was appointed after M. Brisson had made his proposal, preferred the 10,000,000th part of a quarter of the meridian of Paris as unit. The law of the 18th Germinal of the year III. (April 7, 1795) fixed the length of the metre, provisionally, at 3 *pieds*, 11·442 *lignes*. The law of 6 Messidor, year VIII. (June 25, 1800), fixes the length of the metre at 3 *pieds*, 11·296 *lignes*; the difference being −0·146. This length is the legal length of the metre, and is represented by an *étalon prototype* (invariable standard) deposited with the Academy. From 1836 to 1840, M. Puissant found there was an error in the calculation of the meridian distance of Montjouy to Formentera; and, accordingly, he found that the length of the metre should be 3 *pieds*, 11·375 *lignes*. The author of this paper comes to the conclusion, however, that, notwithstanding the slight errors found by MM. Puissant, Bessel, and others, the length of the standard metre, which is only 0·079 *lignes* different from the truth, is to be adhered to, also because of the very great inconvenience any change would cause, which is, after all, not essentially required for the uses of daily life.

Making of Standards of the Metrical System.—M. Jacobi.—This Russian *savant*, who, during his sojourn at Paris, was present at this meeting, read a paper on this subject, with the view of generalising the metrical system by the preparation of a large number of new standards made according to those deposited with the Academy, so that every centre of civilisation in Europe and elsewhere may possess one.

Oxidation of Pyrogallic Acid.—M. Aimé Girard.—The author of this paper points out that, when pyrogallic acid is oxidised in the presence of an acid, the products of its oxidation are different from those which are formed when the oxidation takes place in the presence of an alkali. Among the products there is one, $C_{30}H_{18}O_{18}$, which is a beautiful red-coloured substance, analogous to alizarine, and suitable to be used as a dyeing material. This substance is converted into picric acid by the action of nitric acid.

On Esmarkite.—M. Des Cloizeaux.—Esmarkite is a greyish-green coloured mineral; its fracture is conchoid; hardness holds the middle between apatite and orthose; sp. gr., 2·737. Composition, in 100 parts:—Silica, 47·50; alumina 33·70; lime, 15·40; magnesia, 0·56; soda, 1·84; potassa, 0·59; water, 0·94.

Observations of M. Victor Regnault on a Letter from Dr. Bosscha.—This lengthy paper contains a large amount of valuable matter in reference to thermometers, and among it the following:—The mercurial thermometer is not an instrument fit for being applied to the measurement of temperatures in experiments of precision, since it is not comparable (*manque de comparabilité*). Every mercurial thermometer which is to be applied for rigorously-exact experiments should be previously compared with a well-constructed air thermometer, both for degrees of temperature between 0° and 100°, as well as for higher temperatures. The learned author distinguishes three kinds of mercurial thermometers, viz.:—Standard thermometers, indicating from −10° to +110°; thermometers for high temperatures, graduated from −10° to +350°, but which should not be exposed to a heat higher than 300°; very sensitive thermometers for calorimetrical use, indicating from 0° to +30°. The mercurial thermometer is only a thermoscope; its indications should be converted into degrees of an air thermometer.

Electro-Chemistry: Physical Method to Determine the Molecular Groups which are Decomposed by a Galvanic Current.—M. Bourgoin.—According to this author, the electrolytic decomposition suffered by any compound indicates the grouping of the molecules of which that compound is made up; for instance, when sulphate of soda is decomposed by a galvanic current, it becomes evident, from the products of the decomposition, that the anhydrous salt has suffered dissociation, but not its hydrate; in other words, that the water remains inactive in this process.

Cause of the Ripening of Wines.—M. Béchamp.—The author demonstrates in this paper, at great length, that the same causes which bring on the decay of wine also act in maturing them, and giving them the precious properties recognised as *old*. It is impossible to enter into the details of this subject, which is, of course, practically important only to wine-growing countries; but it appears, after all, that scientific research on this subject is not yet quite exhausted, neither has it so elucidated this matter as to render it of easy practical application.

The American Journal of Science and Arts, vol. xlviii., No. 143, September, 1869.

This number contains the following original papers relating to chemistry and allied sciences:—

Nature and Duration of the Discharge of a Leyden Jar Connected with an Induction Coil.—Mr. O. N. Rood.—This paper is the first part of a memoir read before the National Academy of Sciences. It is copiously illustrated with well-executed woodcuts, which are essential to the understanding of the paper.

On Durangite, a Fluo-Arsenate from Durango, in Mexico.—Mr. Brush.—The author states that he obtained, from a gentleman residing at San Francisco, a bright orange-coloured mineral found at the locality above named. The hardness of this mineral was 5, sp. gr. 3·95 to 4·03; it blackens on being moderately heated in a close tube, but regains its colour again on cooling; at a higher heat it fuses to a yellow glass, and gives a faint white sublimate; it fuses readily in reducing flame, gives a strong arsenical odour, and coats the charcoal with a faint white volatile sublimate. The mineral is only partially attacked by chlorhydric and nitric acids, but is completely decomposed by sulphuric acid, with evolution of fluorhydric acid. Qualitative examination showed the presence of arsenic acid, alumina, iron, manganese, soda, lithia, and fluorine. Search was made for other metallic and mineral acids and chlorine with negative result. The following is the result of quantitative analysis in 100 parts:—Arsenic acid, 55·10; alumina, 20·68; peroxide of iron, 4·78; protoxide of manganese, 1·30; soda, 11·66; lithia, 0·81; fluorine, undetermined, but present in very considerable quantity.

Remarks on the Galvanic Battery.—Mr. Hough.

On Nitric Acid and Chlorate of Potassium as an Oxidising Mixture Applicable to Sulphur, Sulphides, Chromium, Arsenic, and Organic Matters.—Mr. F. H. Storer.—This interesting paper will soon appear in full.

Action of Light on Uranium.—Mr. Bolton.—This memoir contains an historical and experimental review of whatever is known in relation to the action exercised by light upon uranium. The paper is too lengthy for any useful abstraction.

Action of Alkaline Nitrites upon Uric Acid and its Derivatives.—Dr. W. Gibbs.—After referring to the labours of M. Baeyer on this subject, the author describes, at great length, a series of experiments made by him. This paper has, however, been forestalled by a communication of the author written to Berlin, and abstracted by us from the *Berichte der Deutschen Chemischen Gesellschaft zu Berlin* (see CHEMICAL NEWS, vol. xx., p. 131). The original paper was read before the National Academy of Sciences on April 15th last.

On the Meteoric Stone which fell December 5th, 1868, in Franklin Co., Alabama, U.S.—Mr. Brush.—This paper first relates, at length, the history of the circumstances attending the fall of this stone, which, on being received by the author, weighed 615 grms.; sp. gr., 3·31; soluble in HCl, only about 26 per cent. Result of analysis, in 100 parts:—Silica, 51·33; alumina, 8·05; ferrous oxide, 13·70; chromic oxide, 0·42; magnesia, 17·59; lime, 7·03; soda, 0·45; potassa, 0·22; sulphur, 0·23; a trace of nickeliferous iron.

On Lesleyite of Chester Co., Penn., and its Relations to Ephesite of the Emery Formation near Ephesus, Asia Minor.—Mr. Smith.—The author states that some years ago he analysed and described, mineralogically, under *emery*, the last-named mineral. The lesleyite has great similarity therewith. It is of a pearly white colour, and lamellar in structure; scratches glass easily; sp. gr., 3·15 to 3·20; heated before blowpipe, it becomes milk-white, but does not fuse; it is decomposed with great difficulty, by fusing, by carbonate of soda, even with the addition of a little caustic soda. Ephesite, in 100 parts, contains:—Silica, 30·70; alumina, 55·67; lime, 2·55; soda, 5·52; potassa, 1·10; water, 4·91. Lesleyite, in 100 parts:—Silica, 31·18; alumina, 55·00; lime, 0·45; soda, 1·20; potassa, 7·28; water, 4·80.

Artesian Well at Terre Haute, India.—Prof. Guyot.—Under the direction and at the expense of M. Chauncey Rose, a well has been bored, and a very exact account has been made of the thickness of the strata passed through and of the fluids met with:—At 840 ft., show of oil; 1276 ft., lubricating oil; 1335 ft., vein of fresh water; 1629 ft., oil vein; 1658 ft., blue sulphur water; 1710 ft., white sulphur water; 1768 ft., more white sulphur water; 1785 ft., large flow of white sulphur water, at the rate of 6000 gallons an hour. The temperature of the water at that depth is not quoted, neither is any further account given thereof; there is no statement, also, of the height above sea level of the surface of the bore-hole on the ground.

Sulphur Deposits of the Island of Saba, Netherlands West Indies.—Mr. Higgins.—The island of Saba belongs to the volcanic range of the Carribee or Windward Islands. The rock composing almost the entire formation of Saba is trachytic porphyry, which contains glassy felspar and hornblende in crystals, disseminated through a dark reddish coloured base. The sulphur deposit is located on the northern part of the island of Saba, and extends for a distance of more than a mile along the sea line. The stratum of sulphur varies in thickness from 15 to 50 feet; its elevation above sea level varies from 45 to 200 feet. This island has a surface of 16·5 square kilometres (about 9 English square miles, or 5760 acres), and contains 1794 inhabitants; it has been a Netherlands dependency for nearly 200 years, and is a portion of the Government of Curacao, along with Aruba, St. Martin (a portion), Bonaire, and St. Eustatius.

Journal für Praktische Chemie, No. 12, 1869.

This number contains the following original papers:—

Analysis of the Medicated Spring of Tönisstein, and of the Chalybeate Spring at the same place.—Dr. R. Fresenius.—To many of our readers who have made a trip on the Rhine, the Brohl-Thal will have been a pleasant excursion, and to those who made that trip, the two springs just alluded to will be well known. The author of this paper has divided it into two chief sections and several subdivisions. The medicated spring of Tönisstein has been known even so far back as the time when the ancient Romans occupied that country; and in the year 1864, the Prussian Government caused the spring to be properly cleansed out, and, by means of suitably-arranged masonry and tubing, to exclude any extraneous water. The water of this spring, which is evidently forced up by a pretty strong pressure of a constant stream of carbonic acid gas, is quite clear and very sparkling, owing to the carbonic acid gas constantly escaping from the spring; its taste is pleasant, but at the same time saline. The spring yields, on an average, 4908 litres of water in twenty-four hours, while, at the same time, there escapes a quantity of 650 litres of free CO_2; the temperature of the water was found to be 10·8°, while the temperature of the air was, at the time of making the experiment, 19°; the specific gravity of the water at 15° is 1·00598. The author made, first, a very carefully executed qualitative analysis of this

water, and then a quantitative analysis, the results of which are quoted in duplicate—in one case, the carbonates have been calculated as neutral salts; in the other, they are calculated as anhydrous bicarbonates. For each analysis, moreover, the quantities are expressed in duplicate—that is to say, first, upon 1000 parts of water; next, in grains, at 7680 to the Prussian pound. Upon 1000 parts of water, the carbonic acid salts being calculated as anhydrous bicarbonates, there are contained in this liquid:—Sulphate of potassa 0·09900: sulphate of soda, 0·14763; chloride of sodium, 1·41489; iodide of sodium, 0·00001; bromide of sodium, 0·00080; nitrate of soda, 0·00046; phosphate of alumina, Al_2O_3,PO_5, 0·00013; phosphate of soda, $2NaO,HO,PO_5$, 0·00018; bicarbonate of lithia, 0·00622; bicarbonate of soda, 2·57546; bicarbonate of ammonia, 0·00777; bicarbonate of baryta, 0·00008; bicarbonate of strontia, 0·00007; bicarbonate of lime, 0·55116; bicarbonate of magnesia, 1·63697; bicarbonate of protoxide of iron, 0·02949; bicarbonate of protoxide of manganese, 0·00043; silica, 0·02741. Total solid matters, 6·49816; free, that is to say, non-combined carbonic acid, 2·39334. The following substances are present in this water in quantities too small for determination by the balance:—Fluoride of calcium; borate of soda; organic matter, a mere trace; nitrogen, a mere trace. The Tönisstein chalybeate spring yields, on an average, a quantity of 9072 litres of water every twenty-four hours; this water, on being taken at the spring, is a quite clear, briskly-sparkling, refreshing liquid, yet at the same time ferreous to the taste. There escapes along with the water a considerable quantity of free carbonic acid gas, which amounts to some 6·840 litres during twenty-four hours. The temperature of the water of this spring was found to be 11·5°, while at the time this observation was made, the temperature of the air was 18°; the specific gravity of this water at 15° is 1·00270. 1000 parts of this water contain (the carbonates being calculated as bicarbonates):—Sulphate of potassa, 0·05444; chloride of potassium, 0·03575; chloride of sodium, 0·00911; nitrate of soda, 0·00102; phosphate of soda, 0·00040; phosphate of alumina, 0·00045; bicarbonate of lithia, 0·00048; bicarbonate of soda, 0·80325; bicarbonate of ammonia, 0·00410; bicarbonate of baryta, 0·00011; bicarbonate of strontia, 0·00156; bicarbonate of lime, 0·54075; bicarbonate of magnesia, 1·08154; bicarbonate of protoxide of iron, 0·05097; bicarbonate of protoxide of manganese, 0·00372; silica, 0·04107; entirely free CO_2, 2·33600. Total, 5·05382. The following substances are present in unweighable quantities:—Fluoride of calcium, iodide and bromide of sodium, organic matter, borate of soda, and nitrogen; of all merely traces.

Analysis of the Lamscheid Mineral Water.—Dr. R. Fresenius.—This paper is not a sterile account of a chemical analysis, but contains, as introduction, a most interesting historical review of a very anciently-known and renowned mineral spring, situated on the so-called Hundstrück, at an elevation of 1100 feet above the level of the Rhine, taken at Boppardt, and on the great Chaussée, leading from the last-named place towards Simmern and Trier, at a distance of about 12 miles from the Rhine. The water bubbles up from a deep depression in Thonschiefer; the well is properly provided with masonry, to protect it from the entrance of extraneous water. The physical qualities of this water are the following:—Perfectly colourless, briskly sparkling, taste very refreshing, acidulous, somewhat ferruginous, and no smell. The well yields, in 24 hours, about 14,000 litres of water; its temperature is 10·2°, when the temperature of the air is at the same time 20°. The specific gravity of this water at 23·7° is 1·00147. The quantitative analysis of this water, its carbonic acid salts being calculated as bicarbonates, yields, for 1000 parts, the following results:—Sulphate of potassa, 0·004918; sulphate of soda, 0·006905; chloride of sodium, 0·005869; bicarbonate of soda, 0·070088; bicarbonate of lithia, 0·001279; bicarbonate of ammonia, 0·000795; bicarbonate of lime, 0·547639; bicarbonate of baryta, 0·000367; bicarbonate of strontia, 0·000074; bicarbonate of magnesia, 0·207382; bicarbonate of protoxide of iron, 0·071386; bicarbonate of protoxide of manganese, 0·006677[1]; phosphate of alumina, 0·000460; alumina combined with silica, 0·000034; silica, 0·034456; free, that is to say, entirely uncombined carbonic acid, 2·818499. Present in this water, but in too small quantity for estimation, are:—Nitrate of soda, iodide and bromide of sodium, organic matter, and nitrogen, all mere traces. The author quotes in this, as well as in the immediately preceding paper, a very interesting series of analyses of other mineral waters, for the sake of comparison. Space forbids us to abstract or quote these particulars here; suffice it to say that the Lamscheid mineral water is a most excellent chalybeate, and quite equal to the celebrated chalybeate of Pyrmont.

Asparaginic and Glutaminic Acids.—Dr. Ritthausen.—Among the products of the decomposition by the action of strong sulphuric acid upon legumine and conglutine, the latter substance being the proteine compound met with in almonds and lupines, the author discovered asparaginic and glutaminic acids, and, moreover, a substance the nature of which has not been further investigated. In this essay, the investigation of this subject, commenced some time ago, is fully described. Asparaginic acid exhibits a crystalline body, belonging, in that respect, to the rhombic system, soluble in water and alcohol, and consisting, in 100 parts, of:—C, 36·09; H, 5·26; N, 10·53; O, 48·12. Formula, $C_4H_7NO_4$. This acid, which yields, with the oxides of copper and silver, and also with baryta, well-defined salts, is converted, by the action of nitric acid, into malic acid, $C_4H_6O_5$. Glutaminic acid, $C_5H_9NO_4$, when pure, also exhibits crystals belonging to the tetrahedric rhombic system; soluble in water and alcohol; converted into glutanic acid, $C_5H_8O_5$, by the action of nitric acid.

Asparaginic Acid as a Product of the Decomposition of Animal Proteine Compounds.—Dr. Kreusler.—This author has undertaken, for animal proteine compounds, an investigation of a similar nature as Dr. Ritthausen has done for vegetable proteine substances. The writer of this paper has applied, for his researches, caseine from milk, albumen from eggs, and vitelline from the same. These substances were treated separately with a mixture of 3 parts of concentrated sulphuric acid and 6 parts of water to 1 part of substance; the boiling was continued for eight hours. After the necessary purifying process, and the use of oxide of copper to form salts, the author discovered, with perfect certainty, that asparaginic acid is formed in this instance; but glutaminic acid could not be detected. Animal horn, when treated with sulphuric acid, also yields asparaginic acid.

Analysis of the Iodine Containing Water from the Mineral Spring at Roy, near Freistadt, Silesia.—Dr. Redtenbacher.—10,000 parts of this water contain:—Chloride of sodium, 219·680; chloride of potassium, 2·062; chloride of calcium, 21·384; chloride of magnesium, 7·740; bromide of magnesium, 1·016; iodide of magnesium, 0·319; carbonate of magnesia, 1·832; carbonate of protoxide of iron, 0·505; free carbonic acid, 0·594; silica, 0·554; organic matter, 0·432; total of solid substances, 251·6. The iodine spring at Halle contains:—Bromide of magnesium, 0·584; iodide of magnesium, 0·426. The iodine spring at Luhatschowitz contains:—Bromide of magnesium, 0·116; iodide of sodium, 0·237. For both these last springs, the quantities quoted refer to 10,000 parts of water.

Annalen der Physik und Chemie, von Poggendorff, No. 9, 1869.

The following are original papers in this number:—

New Spectroscope, and Contributions to the Spectrum Analysis of the Stars.—M. Zöllner.—The author describes what he calls a reversion spectroscope, and elucidates its mode of action by relating at length a series of observations made by him with this instrument.

Thermo-Chemical Researches.—M. Thomsen.—The basis of this lengthy essay is thus set forth:—Different acids, when neutralised with the same base, evolve unequal quantities of heat; when, therefore, any acid displaces another acid from its combination with that base, this decomposition will be accompanied, either by an evolution of heat or by an absorption of heat, according to the greater or less heat of neutralisation possessed by the free acid or the acid of the salt. The quantity of heat thus evolved or absorbed affords a measure for the degree of decomposition.

Combinations of Alcohol and Water.—M. Mendelejeff.—This paper contains a review of almost every point worthy of notice bearing upon the history of the accurate determination of the density, contraction, and areometrical assay of mixtures of water and alcohol at various temperatures. Another portion of this paper is an essay on the determination of the specific gravity of liquids; to this portion is added the description of a very ingeniously-contrived and neat apparatus, applied for the purpose of taking the specific gravity of liquids, illustrated by a woodcut.

Constant Capillarity of Fused Chemical Compounds.—M. Quincke.

Specific Heat of Air when Kept at a Constant Volume.—M. Witte.

Observations on the Chemical Constitution of Plagioklastic Felspar.—M. Tschermak.—The author does not explain the term *plagioklastic*, but he says the chemical composition of plagioklastic felspars is such that they exhibit isomorphous mixtures of two chemical compounds. [Our readers are reminded that felspar is a mineral of which there exists a great number of varieties; orthoklase, or potash felspar, is $KO,SiO_3+Al_2O_3,3SiO_3$.] The chemical composition of the varieties of this mineral oscillates between two extremes, viz.:—Albite, $Na_2Al_2Si_6O_{16}$, in 100 parts:—Silica, 68·6; alumina, 19·6; soda, 11·8. Anorthite, $Ca_2Al_4Si_4O_{16}$, in 100 parts:—Silica, 43·0; alumina, 36·9; lime, 20·1. The author, who is an eminent mineralogist, enters into a lengthy discussion on the mineralogical characters of felspars, and sharply criticises the labours of some other mineralogists; it appears, however, that the chemical analysis of minerals of complicated composition is not a matter of mathematical certainty. As a proof, the author quotes two analyses of the self-same identical substance, made by two noted chemists, wherein the difference of silica amounts to +2·30 per cent; alumina, −1·95 per cent; lime, +0·53 per cent; soda, −1·44 per cent.

Labradorite from the Närödal.—M. vom Rath.

Elements of Terrestrial Magnetism for Göttingen, July 9, 1869, and the Secular Variations.—M. Cohlrausch.—At latitude 51° 31′, 8 N., longtitude east of Greenwich 9° 56′, 6, the westerly declination of the magnetic needle was, on the above date, 14° 51′, 7; the inclination, 66° 47′, 4; horizontal intensity, 1·8412.

Reflection of Heat on the Surface of Fluor Spar and other Substances.—M. Magnus.—From this memoir we learn that the following substances reflect, at an angle of 45°, the undermentioned quantities of heat:—Silver, between 83 and 90 per cent; glass, between 6 and 14 per cent; rock-salt, between 5 and 12 per cent; fluor spar, between 6 and 10 per cent.

This number contains some papers which have been translated from the *Proceedings of the Royal Society*.

Moniteur Scientifique, October 15, 1869.

This number contains, among its original communications, the following:—

Manufacture of Alkaline Carbonates, and of Carbonate of Lead, and also other Carbonates, by means of a New Chemical Action.—M. Puissant.—When carbonate of baryta in finely-divided powder is suspended through water wherein, simultaneously, a proportional quantity of sulphate of soda is dissolved; and there is next passed through the liquid a current of carbonic acid, which is meanwhile brought to ebullition, double decomposition takes place, sul-

phate of baryta is formed, and carbonate of soda is found in the solution; this solution is filtered, and is employed, by means of a similar reaction, for the production of carbonate of lead. This is effected by the addition of sulphate of lead to this fluid, through which, while it is brought to ebullition, a current of carbonic acid is passed; in this manner, sulphate of soda is again formed, and carbonate of lead is deposited. It should, however, be understood that these reactions do not yield—(1) as regards carbonate of soda, that salt at a less cost than the process by which it is usually made; (2) that the carbonate of lead is neutral carbonate, and is not, therefore, possessed of the requisite covering quality of white lead, $3(PbO,CO_2),PbO,HO$, which is a basic carbonate of lead, which cannot even be made by passing into an aqueous solution of sub-acetate of lead, carbonic acid gas; unless, as is done by M. Ozouf, at St. Denis, near Paris, the quantity of the gas is exactly regulated so as to produce a given quantity of white lead. The two following formulæ exhibit the reactions above alluded to:—

$$BaO,CO_2 + NaO,SO_3 = BaO,SO_3 + NaO,CO_2.$$
$$PbO,SO_3 + NaO,CO_2 = PbO,CO_2 + NaO,SO_3.$$

Quantitative Analysis of Raw Soda (Soda Ash) and Caustic Soda.—M. Jean.—After referring to the volumetrical methods devised by the late M. Gay-Lussac, and pointing out some inconveniences of this method, the author states that he proceeds as follows:—Take 4 grms. of the sample to be analysed, and dry completely at from 110° to 120°; the difference between the weight of the quantity originally taken and the weight after drying gives the quantity of water. Take 1 grm. of this dried material, place it in a glass tube, and pass a current of *dry* carbonic acid gas over the substance for about an hour; dry it again at 110°, to drive off any mechanically-adhering carbonic acid; place the substance upon a filter, and exhaust with tepid water (32°), until the wash water is no longer precipitated by chloride of barium. The filtrate is collected in a glass balloon with flat bottom, and chloride of barium is added to it. The liquid is left to settle, and, on having become quite clear, is drawn off from the precipitate, by means of a pipette, and the precipitate of carbonate of baryta is collected on a tared filter, washed with boiling water, dried, and weighed. If there happen to be sulphates present, the sulphuric acid is precipitated, along with the carbonate of baryta, as sulphate of that base, and the weighed carbonate of baryta is, therefore, washed with water acidulated with hydrochloric acid, again washed with warm water, and, after drying, weighed. In order to estimate the carbonate of soda, 1 grm. of the dried sample is taken, dissolved in water, precipitated with chloride of barium, the precipitate is collected on a tared filter, and, after having been washed and dried, there is deducted, from the weight found, the weight of the sulphate of baryta. The difference of the weights of the carbonates of baryta found by these two operations indicates the quantity of carbonate of baryta which, by calculation, has to be converted into caustic soda; the second assay gives the quantity of carbonate of soda. In order to estimate the sulphide of sodium contained, 1 grm. of the dried material is again taken; this quantity is dissolved in water, and estimated according to M. Gay-Lussac's method. Let us suppose that this assay has given a quantity of carbonate of soda equal to A, and that our previous operations gave us B of caustic soda and C of carbonate of soda; calculate the quantity of caustic soda, B, into C', as carbonate of soda—$C' + C = C'''$, total quantity of carbonate of soda indicated by the gravimetrical assay. The difference between the quantity, A, of carbonate of soda indicated by the volumetrical method, and C''', that found by the gravimetrical method, indicates the quantity of carbonate of soda which has to be calculated as sulphuret of sodium.

Preparation of the Sulphuret of Sodium by a New Process.—M. Jean.—After referring to the difficulties attending upon the preparation of sulphuret of sodium, by igniting a mixture of sulphate of soda and carbonaceous matter, whereby a pure product can never be obtained, the author states that he has found the following process to yield very satisfactory results:—25 kilos. of dry sulphate of soda, 75 kilos. of sulphate of baryta, 10 kilos. of powdered charcoal, and 15 kilos. of powdered pit-coal, are intimately mixed and ignited in an ordinary soda furnace. From time to time, a small sample of the ignited mass is taken, and tested by being dissolved in water, filtered, and to the filtrate a drop of a solution of sulphate of soda is added. As soon as a precipitate of sulphate of baryta ensues, the operation is finished, and the ignited mass is at once transferred to iron vessels, which can be closed with a lid, so that access of air is excluded while the mass cools down; after cooling, the crude sulphuret is placed in wrought-iron tanks, and boiling water is added and ebullition kept up for some time; some sulphate of soda is added, in order to precipitate excess of sulphide of barium. After the liquid has become clear, it is drawn off by means of a syphon, and the solution evaporated to dryness. The sulphuret of sodium obtained by this process is quite free from any undecomposed sulphate, from sulphuret of iron, from silica, and from alumina. By this process, the fire-bricks of the furnace are not acted upon, and the ignited mass is in pulverulent, and not in fused state, and therefore no grinding is required. When, instead of sulphate of soda, sulphate of potassa is used, an excellent sulphide of potassium is obtained, which would be greatly in demand for the manufacture of ferrocyanide of potassium by Géli's process, and for the artificial preparation of water impregnated with alkaline sulphides to be used for bathing purposes.

Purifying Bromide of Potassium.—Dr. Baudrimont.—The bromide of potassium is first qualitatively tested for the presence or absence of iodide of potassium; if that salt happen to be present, it is removed in the following manner:—About 10 grms. of the impure bromide are dissolved in a sufficient quantity of distilled water; a solution of bromine in water is then added in excess, this solution being preferable to bromine itself, as being more readily managed. The liquid is then heated to boiling, and kept so until no more vapours of iodine are given off. The liquid is next evaporated to dryness, in order to eliminate the excess of bromine. In this way a bromide of potassium is obtained free from iodide, but which may yet contain chloride of potassium.

Annales de Chimie et de Physique, October, 1869.

This number contains the continuation of an essay—

New Researches on Thermo-Chemistry.—M. Berthelot.—This paper is divided into several sections, each bearing a separate title:—Decomposition of organic substances by heat; action of the electric spark upon marsh gas; union of nitrogen in free state with acetylen; direct synthesis of hydrocyanic acid; formation and decomposition of sulphide of carbon; chemical equilibrium between carbon, hydrogen, and oxygen; the spectra exhibited by some compound substances when exposed to gaseous mixtures in state of equilibrium; influence of pressure upon chemical equilibria, and especially on the reactions taking place between carbon and hydrogen.

Memoir upon the Determination of the Lengths of the Waves of the Metallic Spectrum Rays.—M. R. Thalén.

Second Memoir on Supersaturation.—M. Lecoq de Boisbaudran.—This paper is the first instalment of a second memoir of the subject named at the head. The author says—"I intend to divide this essay into two sections; in the first of these, I shall record the action of some isomorphous substances upon the supersaturated solutions of the sulphates of the oxides of iron, nickel, copper, cobalt, magnesia, and zinc; in the second portion of this essay will be found described the action of the same isomorphous substances upon supersaturated solutions of two of the above-named sulphates at the same time.

Revue Hebdomadaire de Chimie, October 7, 1869.

This number contains:—

Description of an Air-Pump with Free Plunger.—M. Deleuil.—There is added to this paper a well-executed woodcut. It appears that the vacuum which can be maintained by this air-pump is more perfect than has hitherto been obtained by any ordinary pump of the sort. From recipients of 250 litres capacity, the air can be withdrawn so as to leave only 10 m.m. pressure in a quarter of an hour. There is, with this machine, no need for the use of any oil to counteract friction. The piston (plunger) is double-acting, and it moves as easily at the beginning of the operation of pumping as at the end, with a very rarefied air. The free space between the plunger and the body of the pump is only 1-50th of a m.m.

October 14, 1869.

This number contains:—

Use of Electric Alarums to Indicate a Certain Temperature. MM. Besson and Knieder.—The authors have constructed a set of thermometers, through the tubes of which are soldered two small pieces of platinum wire, which are not in metallic contact, until the mercury just rises to the height at which the wires have been placed. Since the latter are in contact with conducting wires to a suitable galvanic apparatus, the instant the mercury makes metallic contact, an alarum is sounded; and this may, of course, by proper adjustment, be affected at any temperature, which, for some purpose or other, should not be exceeded. The instrument is intended for industrial use.

Glycerine Soap.—M. Heeren.—Take 100 parts of oleine of commerce, pour it either in a glass flask (when only a small quantity of soap is intended to be made, or in a cauldron for large quantities), add 314 parts of glycerine of 1·12 specific gravity, heat to 50°, and then add 56 parts of an aqueous solution of caustic potassa (sp. gr., 1·34), and stir the mixture well. The soap is readily and rapidly formed; but the liquid has to be kept at rest for twenty-four hours, and then exhibits a mass of the consistency of honey, in which state it remains. Filtration may be required, but is troublesome and slow.

Test for Albumen.—Dr. Méhu.—Take of crystallised carbolic acid, one part by weight; of commercial acetic acid, the same quantity; of alcohol at 90 per cent, two parts; mix, and keep in a bottle. This fluid is intended to detect albumen in urine; and for that purpose, to 100 grms. of this liquid (urine) are added 2 c.c. of commercial nitric acid, and next, after thorough mixing, 10 c.c. of the carbolic acid solution. The reaction is stated to be very superior to the use of nitric acid alone.

Cosmos, October 16, 1869.

Liqueur de la Grande Chartreuse.—Dr. Chevalier.—According to this author, this celebrated liqueur, made at the Abbey of the name, near Grenoble, is composed of:—Essence of *melissa citrata*, 2 grms.; essence of hyssop, 2 grms.; essence of angelica root, 10 grms.; essence of best mint, 20 grms.; essence of nutmeg, 2 grms.; essence of cloves, 2 grms.; and 2 litres of rectified spirits of wine, of best quality. The liquid is artificially coloured, either with turmeric or any other suitable material.

Les Mondes, October 14, 1869.

Biography of A. von Humboldt.—M. C. Bruhns.—The Director of the Royal Observatory at Berlin has stated that he intends to publish a scientific biography of von Humboldt, with the co-operation of a great

number of German *savants*. The first portion of this work is entrusted to M. Lallemand, who has in his possession a large number of documents and manuscripts, never before published, relating to the late *savant's* life. The second portion of this work will consist of eight separate chapters, each treating of a peculiar science; and each chapter will be edited by the most eminent men in the department of science it treats of.

Removing Stains caused by Photographic Chemicals from the Hands.—M. Fortin.—Referring to the use of cyanide of potassium, and of iodide of potassium, and iodine for this purpose, the author says the first endangers health, and even imperils life; the second is very expensive. The author recommends, instead, to wash the hands with a concentrated solution of either sulphate or chloride of zinc, to which some acid is added at the same time. The deepest and blackest stains should be touched with metallic zinc, whereby the reduction of the oxide of silver or that of the gallate of iron is promoted, and all metallic stains adhering to, or penetrating in the skin removed. Since most of the salts of zinc are colourless, and soluble in water, the hands become soon quite clean. They should then be washed, first with pure water, and next with soap and water.

Preparation of Caustic Baryta for Industrial Purposes.—M. Nicklès.—Four operations are required—(1) Conversion of native sulphate of baryta into sulphide of barium is effected in a continuous manner, in a peculiarly-constructed furnace, the sulphate being previously mixed with a reducing substance; (2) the conversion of the sulphide of barium into hydrate of baryta by means of hydrated oxide of zinc; (3) dehydration of the hydrate of baryta by ignition along with saw-dust; (4) regeneration of the substance which has served for the desulphuration of the sulphide, and obtaining of sulphur.

Cultivation of Cotton in Southern France.—M. Croze-Mugnan.—The author states that, after having made a series of experiments for several years, he is convinced that the cultivation of the *Gossypium herbaceum* will be attended with excellent success in the warmer districts of the south of France.

New Theory of Gravitation.—M. Leray.—We only give the title of this paper, which is well worthy the notice of natural philosophers.

We learn from this paper that the Physical Society at Rotterdam, known as the Bataafsch Genootschap voor Natuur Schei en Werktiugkunde, has caused a number of medals to be struck to commemorate the hundredth anniversary of its existence. This medal, which is stated to be excellently well-made, bears upon the obverse the inscription, "Certos feret Experientia Fructus;" upon the reverse, "Societas Philosophiæ Experimentalis Batava Roterodami Centesimum Natalem Celebrans. In Memoriam Stephani Hoogendijk, Fundatoris, MDCCLXIX—MDCCCLXIX." This Society has a large and very valuable collection of physical instruments, a fine library, and holds its meetings and lectures in the very extensive second-floor halls of the Royal Exchange at Rotterdam.

October 21, 1869.

New Process for Concentrating and Utilising the Sun's Rays.—M. Delaurier.—The author proposes, for this purpose, a truncated cone, open at both ends, and lined inside with polished silver, the sun's rays being admitted by the largest opening. Since the angle of reflection is equal to the angle of incidence, all direct, or reflected rays, will be united at the narrower end of the cone. It is clear that, the greater the length of the cone, the less the opening of its top need be, and the greater will be the concentration of heat. The author's paper, to which a woodcut is added, enters into a discussion on the advantage of this contrivance above the use of lenses and mirrors; and the author very enthusiastically surmises that the heat of the sun's rays may be so concentrated as to serve, instead of the combustion of fuel, for various purposes, especially in countries where, as in Algeria, the heat and splendour of the sun is more permanently felt.

Ancient and Modern Industry of the Chinese Empire.—Among the *accusés de reception*, we find, under the above heading, "d'Après des Notices Traduites," par M. Stanislas Julien, et accompagnées de notices industrielles et scientifiques, par M. Paul Champion, Préparateur de Chimie au Conservatoire des Arts et Métiers, Ancien Délégué de la Société d'Acclimatation en Chine et au Japon; 1 vol., large octavo, 254 pages, and 13 lithographic plates. This is an authentic work, having been faithfully translated from the Chinese language by the best scholars versed in that language in France, while M. Champion has been residing a long time in China, and describes what he has actually seen. The work embraces the following subjects:—Fuel, salt, lime, sulphur, talc (magnesia minerals), nitrate of potassa (saltpetre), gunpowder, soda and potash, mineral pigments, alum, metals, vegetable colours and dye materials, vegetable wax (from trees), varnishes, oils, candles, ink, paper, printing, vegetable textile fibres, washing of garments, tobacco, papaver and opium, sugar, glucose, preservation of eggs, alimentary *regime* and wages, matches, amber, camphor, rearing of fish, magic lantern, boring of wells, silk, and some minor subjects. The entire work is full of extremely useful information, even for civilised Europe.

NOTES AND QUERIES.

Tungstate of Soda, &c.—Can any of your readers give us the names of manufacturers of tungstate of soda and tungstate of chrome?—J. C.

Bichromate of Potash.—Can any of your numerous readers inform me if bichromate of potash is manufactured anywhere else except in Scotland?—BICHROME, Glasgow, October 27, 1869.

Detection of Prussian Blue in Black Ink.—Can any of your readers kindly inform me how to detect Prussian blue in black ink, that is, if any has been used to give it a blue colour; and also if there is a means of telling when there is logwood used in the preparation, or galls.—J. KAYE.

Footpaths.—I wish to lay down a cheap footpath. Can any of your readers inform me of a compound that will harden and not be affected by the weather? I was thinking of using a mixture of tar pitch, sand, and gravel. What can I add to prevent it softening with the heat of the sun, if there is nothing cheaper, will cement do it? and if so what proportion must be used? Many of the streets in Paris are made with a compound put down in the form of powder, which after having been rolled with heavy rollers, becomes very hard, and forms a smooth and durable road. What is the mixture used?—ROADWAY.

Purification of Glycerine.—M. Kunath.—The glycerine used largely in those parts of Central Europe where the winters are severe for the filling of wet gas-meters has to be purified again, and concentrated after it has been in use for some time. For this purpose, the impure glycerine is poured in a large vessel, and, upon every hundredweight of glycerine, 10 lbs. of iron-turnings are added; the whole mass is thoroughly stirred up, and this stirring repeated for some hours every day for a fortnight. After that period, the mixture is left quietly standing for some weeks, when the clear liquid is withdrawn from the sediment by means of a syphon, concentrated by evaporation, and again used in the gas-meters. The iron-turnings act mechanically as well as chemically: sulphuret of iron is formed, and the formation of this substance aids the precipitation of tarry matters.—*Dresdener Gewerbe Vereins Zeitung*.

Rendering and Bleaching Tallow.—Will any of your practical correspondents kindly give me the best and cheapest methods of rendering and bleaching tallow from rough fat, and how much per cent of tallow should be realised from rough fat rendered by the aid of sulphuric acid (say about 1 per cent of acid); or is that quantity of acid too much, as I find a great variation in the quantity obtained from present results; the quantity of rough fat rendered at each operation is about 3 tons. Is bleaching with black oxide of manganese and sulphuric acid considered the best, or a good method? as I find, in practice, it gives a yellow tinge—occasionally. What may be the cause? as I cannot get the tallow as white as it ought to be; it is more like beef tallow, although it is rendered from a mixture of beef and mutton fat. What substance can be used to precipitate impurities arising from rendering and bleaching when the process of washing is going on? Also, is there any method that can be used to prevent tallow *seeding* (a term generally used in the trade, which denotes the separation of the oily portion from the solid parts), besides continual agitation, until sufficiently cold to be packed?—A TALLOW MELTER.

MEETINGS FOR THE WEEK.

THURSDAY, November 4th.—Chemical Society, 8. Discussion on Dr. Williamson's Discourse "On the Atomic Theory."

TO CORRESPONDENTS.

ERRATUM.—Page 201, column 1, bottom line, insert, after 120 c.c., the word *aniline*.

Ferrum.—Please forward your address.

BOOKS RECEIVED.

Exercises in Practical Chemistry, by A. G. V. Harcourt, F.R.S., and H. G. Madan, F.C.S.

Chemistry: General, Medical, and Pharmaceutical, including the Chemistry of the British Pharmacopœia. By John Attfield, Ph.D. London: John Van Voorst.

A Pharmacopœia, including the Outlines of Materia Therapeutics, for the use of Practitioners and Students of Veterinary Medicine. By Richard Tuson, F.C.S., &c. London: John Churchill and Sons.

Just published, demy 8vo., price 6d.

On English and Foreign Alkalimetrical and Chlorimetrical Degrees, by John Pattinson, F.C.S. Read before the Newcastle Chemical Society.

London: CHEMICAL NEWS Office, Boy Court, Ludgate Hill, E.C.

Professor Tennant, F.G.S., will deliver a Course of Lectures on MINERALOGY applied to GEOLOGY and the ARTS, at King's College, London, on Wednesday and Friday mornings, at nine o'clock, during October, November, and December, commencing October 8th. Fee, £2 2s.

A Course of Lectures on MINERALOGY and GEOLOGY will also be delivered, on Thursday evenings, at eight o'clock. These begin October 14th, and will be continued to Easter, 1870. Fee, £1 11s. 6d. Professor Tennant gives PRIVATE INSTRUCTION in Mineralogy and Geology, Illustrated by a large number of Specimens, at his Residence, 149, Strand, W.C.

VOL. XX. No. 519.

ON THE

METHODS OF ANALYSIS AND THE COMPOSITION OF VARIOUS CHEMICAL MANUFACTURING PRODUCTS.

By M. GASTON TISSANDIER.

(Continued from p. 95.)

SULPHATES OF POTASH.

ALMOST all commercial sulphates of potash are obtained from beet-root salts, or by treating the ashes of seaweed. All specimens, whatever their origin, may, however, be analysed in the following manner.

Mode of Analysis.—Weigh 25 grms. of the sulphate in question, and dissolve in distilled water; filter, to separate the insoluble substances, and wash the filter until the clear liquid, collected in a graduated measure, occupies the volume of 500 c.c.

Alkalimetric or Acidimetric Standard.—Plunge sensitive litmus paper into the solution, and ascertain whether it be alkaline or acid. In the first case, take the alkalimetric standard in 100 c.c. In the second, which is less frequent, obtain the acidimetric standard by means of a standard potash solution.

Sulphuric Acid.—The sulphuric acid is estimated in 10 c.c. of the solution (0·5 grm.), by means of chloride of barium.

Chlorine.—Determine the proportion of chlorine in 50 c.c. (2·5 grms.) by standard nitrate of silver.

Potassium.—To estimate this exactly, add to 10 c.c. of the solution a few drops of chlorhydric acid and of a standard solution of chloride of strontium, in such quantity that all the contained sulphuric acid may be precipitated in the state of sulphate of strontia. Let it stand for twelve hours; filter, and, after washing the precipitate, evaporate the filtered liquid almost to dryness. Add a slight excess of bichloride of platinum, and evaporate with the precipitated chloroplatinate of potash, which must be collected and weighed, as directed under the article "Salts."* The transformation of the sulphate into chloride by the chloride of strontium is indispensable, if an exact result be desired. Were the bichloride of platinum added directly to the solution of the sulphate, the potash would not be entirely precipitated; the precipitated chloroplatinate would contain, as has been already proved, a certain proportion of non-decomposed sulphate.

Moisture.—The salt is dried on a stove, at 110°, or in a platinum crucible.

Calculation of the Analysis.—The potassium found is converted into sulphate of potash, and it is seen by calculation if the quantity of sulphate of potash so formed contains the proportion of sulphuric acid found. If there is an excess of sulphuric acid, it is converted into sulphate of soda. If, on the other hand, the quantity of potassium is too considerable to saturate the whole of the sulphuric acid, the excess must be combined with chlorine and carbonic acid, Some sulphates contain chlorhydric acid. Its presence may be accounted for by the addition of sulphuric acid in the manufacture. The sulphuric acid is used to transform the carbonate of potash into sulphate, but, if added in too great excess, it will act upon the chloride of potassium, and give rise to an equivalent quantity of chlorhydric acid.

CAUSTIC SODA.

Specimens of commercial caustic soda generally present the appearance of greenish or yellowish masses, which must be quickly crushed into small fragments before analysis. For this purpose, it is best to employ a cast-iron mortar, perfectly clean, and previously warmed, in order that the soda may not absorb atmospheric moisture in any appreciable quantity during the crushing. Commercial caustic sodas always contain chloride of sodium, sulphate and carbonate of soda. The method by which the exact proportion of these constituent elements may be ascertained will now be shown.

Total Alkalimetric Standard.—Weigh 5 grms. of caustic soda quickly, and dissolve them in water. Take the alkalimetric standard in the cold, by means of ordinary standard sulphuric acid. The total standard of caustic soda is sometimes from 108° to 110°.

Estimation of Caustic Soda.—Weigh 5 grms. of caustic soda, and throw them into a stoppered flask containing about 400 c.c. of water: distilled water, previously boiled, to avoid its containing carbonic acid, is the best. When the soda has been dissolved by stirring, add an excess of chloride of barium, which will precipitate the sulphate of soda as sulphate of baryta, and the carbonate of soda as carbonate of baryta. The liquid thus formed must be filtered, care being taken to close the flask as much as possible, and to cover the top of the filtering funnel with a plate of glass, to avoid the action of the air. It is especially needful to place the funnel in a flat-bottomed flask, that the filtered liquid may not come in contact with the ambient air. Litmus is added to the filtered liquid, and the alkalimetric standard taken in the cold. The addition of normal sulphuric acid solution causes the formation of a precipitate of sulphate of baryta, due to the excess of chloride of barium; but this occurrence is of no importance. The number of divisions on the burette must be read at the exact moment when the last drop of standard liquid causes the solution to change from violet-blue to vinous-red. This number gives the standard of causticity, which, again, shows, by calculation, the quantity of caustic soda according to the following equation:—

$$\frac{\text{Standard or number of divisions on the burette}}{x} = \frac{49(SO_3,HO)}{40(NaO,HO)}$$

The standard of causticity obtained, deducted from the total standard, gives the standard corresponding to the carbonate of soda, and, consequently, the proportion of

the latter salt. To be more exact, this determination should be verified in the following manner.

Carbonate of Soda.—The filter containing the sulphate and carbonate of baryta will also serve to determine the quantity of carbonate of soda. Pour upon the filter water acidulated with pure chlorhydric acid, which will dissolve only the carbonate of baryta, without acting at all upon the sulphate. The filtered liquid contains, in the state of chloride of barium, all the baryta of the carbonate of baryta. Sulphuric acid is now added, and, after standing for twelve hours, the precipitated sulphate of baryta is weighed. This sulphate of baryta is transformed, by calculation, into carbonate of baryta; or, directly, by equivalents, into carbonate of soda; and thus the quantity of the latter salt contained in 5 grms. of caustic soda is ascertained.

Sulphate of Soda.—The amount of sulphuric acid in caustic soda is estimated in 5 grms. of the specimen under analysis, by means of chloride of barium (see article, "Salts" *ante*). If it be desired to omit this experiment, the filter used to obtain the standard of causticity may be immediately weighed, after rinsing with chlorhydric acid, to remove the carbonate of baryta. In this case, in order that the estimation may be exact, the precipitate of carbonate and sulphate of baryta must be allowed to stand for twelve hours.

Chloride of Sodium.—Weigh 2·5 grms. of caustic soda, and throw into a stoppered flask; dissolve it in water, acidulate with pure nitric acid, and estimate the chlorine with the standard nitrate of silver liquid (see article, "Salts," *ante*).

Moisture.—The moisture contained in caustic soda is estimated by operating in a silver crucible, which must have a cover. It is weighed empty, and again weighed with a small quantity of caustic soda. Heat is carefully applied to fuse the soda: great precaution must be used that the temperature may not be too much increased, in order to avoid projections. The action of too much heat would not only remove the moisture, but also part of the water in combination with the caustic soda, and the erroneous figure thus obtained would be, in that case, much too high. The caustic soda, once fused, is again weighed, and the three weights thus obtained are the bases of a simple calculation, which will give the quantity of humidity contained.

Calculation of the Analysis—Some of our readers have asked for more ample details respecting the calculations necessitated by these modes of analysis. We will, therefore, re-produce an example of the analysis of caustic soda.

Direct Results of an Analysis of Caustic Soda.

Total standard, 109°.

Standard of causticity, 106°.

Number of divisions of the graduated burette of nitrate of silver (estimation made on 2·5 grms.), 101 divisions.

Weight of the sulphate of baryta in 5 grms., 0·195 grm.

By deducting the standard of causticity from the total standard, the standard of carbonate of soda is obtained. Say, 109 − 106 = 3. To obtain the quantity of carbonate of soda corresponding to a standard of 3 degrees, it is only necessary to state the following equation:—

$$\frac{3}{x} = \frac{49(SO_3HO)}{53(CO_2NaO)}$$

Whence x (carbonate of soda) = 3·44 per cent.

The standard corresponding to the caustic soda is 106°. Consequently,

$$\frac{106}{x} = \frac{49(SO_3,HO)}{40(NaO,HO)}$$

will give x (hydrated caustic soda) = 86·53 per cent.

Commercial caustic soda is generally sold according to the quantity of anhydrous soda, NaO. To obtain NaO, state the equation—

$$\frac{86{\cdot}53}{x} = \frac{40(NaO,HO)}{31(NaO)}$$

Whence x (NaO) = 67·306 per cent,

For the chloride of sodium, the standard liquid containing nitrate of silver in such a quantity that one division corresponds to 1 milligramme of chlorine, state the equation—

$$\frac{101}{x} = \frac{35{\cdot}5(Cl)}{58{\cdot}5(NaCl)}$$

Whence x = 1·66. But 2·5 grms. were operated upon; it is, therefore, necessary to multiply by 40 to obtain the quantity of chloride of sodium in hundredths.

1·66 × 40 = 6·64, or ClNa = 6·64 per 100.

The sulphate of baryta, in 5 grms., weighs 0·195 grms. Consequently, the equation—

$$\frac{0{\cdot}195}{x} = \frac{116{\cdot}5(SO_3BaO)}{71(SO_3,NaO)}$$

will give x = 0·118 × 20 = 2·36 of SO_3NaO per cent.

The analysis is thus formularised, after estimating the moisture, which we will suppose to exist in the specimen under analysis in the proportion of 1·02 per cent.

Moisture	1·02
Chloride of sodium	6·64
Sulphate of soda	2·37
Hydrated caustic soda	86·53
Carbonate of soda	3·44
	100·00

Oxide of sodium (NaO) = 67·306 per cent. We have omitted the calculation relative to the determination of the carbonate of soda by the carbonate of baryta, as it is sometimes unnecessary. Supposing the above analysis to have been scrupulously exact, the carbonate of baryta dissolved in pure chlorhydric acid, and precipitated as sulphate of baryta, would yield a weight of 0·379 of sulphate of baryta.

$$\frac{0{\cdot}379}{x} = \frac{116{\cdot}5(SO_3BaO)}{53(CO_2NaO)}$$

would give x = 0·172 as the quantity of carbonate of soda contained in 5 grms. Multiplying by 20, the product would be—Carbonate of soda = 3·44 per 100.

	French sodas.			English sodas.		

Sodas of a much poorer quality than those whose composition we have just given are occasionally to be met with. We subjoin an example of the analysis of one of these poorer caustic sodas. Caustic sodas are generally sold according to the quantity of anhydrous oxide of sodium (NaO); and the analyses are usually formularised in the above manner. It will be seen from the above figures that the products of English manufacture are much richer than the French. Some few French manufacturers have already brought the production of caustic soda to perfection; but much progress still remains to be realised in France with respect to this manufacture.

(To be continued).

ON MICROSCOPICAL MANIPULATION.*

By W. T. SUFFOLK, F.R.M.S.

(Continued from p. 209.)

THE microscopist, in the course of his studies, will find a very large class of substances for which the processes described in the preceding chapter are of no avail, owing to the impossibility of drying them without materially affecting their structure. The preservation of such substances has always been a matter of some trouble; and beginners are frequently deterred from attempting the processes of fluid mounting by supposing that the difficulties are of an insurmountable kind.

There is also a prejudice against objects mounted in fluid, owing to their supposed want of durability. There is, no doubt, some ground for this objection if the ordinary fluid-mounted objects only are considered. These are of necessity manufactured cheaply and in large numbers, and but little care can be bestowed upon their preparation. But, if the cabinets of our best manipulators are examined, the evidence will be found rather in favour of than against fluid mounting, provided care be taken to adopt the best processes, and carry them out carefully; the causes of failure being rather attributable to bad workmanship than to defects in the mode of preparation. Instances are on record of objects mounted in fluid as long ago as twenty years being still in good preservation.

The subject naturally divides itself into two parts; the processes connected with the enclosing of the object in its cell, and the consideration of the nature of the fluid media employed as preservatives.

The object to be mounted in fluid will nearly always require some previous preparation, excepting in those cases where it is free from included air, and the fluids contained in its tissues are readily miscible with the preservative employed. This preparation consists in keeping the tissues required for preservation immersed either in the fluid in which they are to be mounted, or some other which is capable of combining with it without injurious chemical change. This soaking will occasionally occupy a considerable time; but it may be materially expedited by making use of the air-pump, which will ensure the saturation of the tissue, and assist in the removal of air that may be held within it. The process is exactly the same as that adopted on the large scale for the preservation of railway-sleepers, by impregnating them with creosote; and, in another operation (one that more closely approaches the subject under consideration), Manfield's patent for making pickles, in which the vegetables to be treated are saturated in a few minutes with vinegar, by being submitted to its action in a vessel from which the air has been exhausted; a process which took so long a time in the ordinary way, that manufacturers, to save the loss of capital involved in using vinegar, employed brine, which was afterwards removed by strong acetic acid, greatly to the detriment of the resulting manufacture, both as to flavour and wholesomeness. This is now obviated by the new process, the pickles produced by which closely resemble those made at home.

* The substance of a course of lectures delivered to the members of the Quekett Microscopical Club, January—April, 1869.

Although the air-pump is useful where substances peculiarly liable to retain air (such as large anatomical preparations) are being operated upon, its use can generally be dispensed with for ordinary purposes, a prolonged soaking being sufficient in most cases.

In mounting an object in fluid, a cell of suitable size and depth is to be selected, and care taken that it is properly cleaned. It is then filled with the mounting fluid, and should be rather over than under filled. The object is now placed in the cell, unless circumstances have rendered it advisable that this should be done previously. The preparation, at this stage, should be carefully examined, with a view to the detection of air-bubbles. They are especially liable to adhere to the lower part of the cell, where it joins the glass slide. They are best dislodged by drawing the point of a needle round the interior of the cell. Floating bubbles may be broken or removed by lightly touching with a pointed fragment of blotting-paper.

The cover glass is to be placed upon the cell as directed in balsam mounting—letting one edge touch the cell first; and, as in that process care was taken to keep everything dry, in fluid mounting we should adopt the opposite course of treatment. To secure the adhesion of the mounting fluid to the cover, and lessen the chance of including an air-bubble, it is well to moisten the cover by breathing on it just before placing it on the cell.

The surplus fluid is best removed, in the first instance, by drawing it off with a curved and sharp-pointed pipette, made in the form of an ordinary blow-pipe. The use of this contrivance will generally allow the floating cover to be brought in contact with the top of the cell without the risk of flooding its upper surface, which is nearly sure to take place when the cover is pressed down suddenly, and will give trouble to remove when viscid fluids like glycerine and oil are used. When as much of the fluid is removed as can be conveniently taken up with the pipette, the rest is absorbed by the careful use of fragments of blotting-paper. Care must be taken not to carry this process too far, as, if too much of the fluid is absorbed, an air-bubble may enter, which will necessitate the removal of the cover and a repetition of the operation. The moisture being cleaned off the outside, the cell is ready to receive its first coat of varnish, which is to be applied with a small brush, and care should be taken to fill the angle at the contact of the cover and cell, and to include in the ring of varnish a small portion of the edge of the cover. This first coat of varnish must be put on by hand, as the adhesion of the cover is too slight to bear the action of the turn-table, which machine, however, may be employed with advantage in laying on the second and subsequent coats, as, by its use, greater neatness and rapidity are attained than are possible by painting on the varnish by hand.

The best and most durable cement for securing the covers of objects mounted in fluid is the varnish known as japan gold-size, the principal constituent of which is boiled linseed-oil. It is easily obtained at any varnish shop. It is best kept for use in the collapsible tubes recommended for holding Canada balsam. If kept in a bottle, it absorbs air, thickens, and loses, to some extent, its drying properties. This varnish is remarkable for its elasticity and toughness when dry, which may readily be proved by scraping a portion, which will be found to come

away in shreds instead of chipping, as many other varnishes do. Glycerine and castor-oil, both valuable mounting fluids, have the unfortunate property of dissolving gold-size; therefore, in using these media, it is necessary, before putting on the coatings of gold-size, to apply two or three coatings of the liquid glue previously mentioned. This varnish is impervious to oil and glycerine, but is too brittle when dry to be trusted alone. The liquid glue will be found effectually to protect the gold-size, with which the preparation is to be finished. This precaution is not required when using media which do not injuriously affect gold-size, such as weak alcohol and water, saline solutions, camphor and creosote water, &c.

Some microscopists make use of asphalte or Brunswick black for securing the cover. They have the fault of being brittle, which, however, is said by Dr. Beale to be remedied by the admixture of a small portion of solution of india-rubber in naphtha. The author's experience of this cement is rather unfavourable. It may, however, be owing to having used a bad specimen; as it is probable that many kinds of Brunswick black are manufactured, and they are likely to vary extremely in quality. However, as gold-size is so reliable a cement, and so easily procured, there is no occasion to risk the use of a varnish whose properties are somewhat uncertain.

Should the mounting fluid be one which leaves a deposit on drying (which is the case with saline solutions), or be difficult to clean off (like glycerine), after the first coat of varnish is dry, the slide should be washed, either by holding under a partially-open tap, or by means of the ordinary wash-bottle. If this precaution is not taken, the adhesion of the cement is rendered uncertain, and neglect of this matter is a not unfrequent cause of leakage. If necessary, this washing must be repeated after the second coat of varnish. With oil, a somewhat different treatment is needed. The cleaning is best effected with a camels'-hair brush, charged with turpentine or benzol.

The slide should not be put away in the cabinet until it has received at least six or eight coats of gold-size. No varnish should be laid on thickly, otherwise it is liable to remain fluid in the interior, although apparently hard outside.

In commencing the practice of fluid mounting, it will be advisable for the student to make his first trials with some such fluid as camphor-water or diluted alcohol, as the difficulties of cleaning, &c., are much less than with saline solutions or glycerine.

A very ingenious process of fluid mounting forms the subject of a communication by Mr. T. C. White to the Quekett Microscopical Club (*Journal of the Quekett Microscopical Club*, vol. i., p. 147). He forms a cell with a thick varnish, made by dissolving gum damar in benzol. This is done by holding a brush charged with it against a slide while revolving on the turn-table. The cell will be ready in a few minutes, as it is used while half dry. The fluid and object are placed in the cell, and the cover glass put on, and pressed down into the cement, which adheres most tenaciously to wet glass. The surplus fluid is to be removed with blotting-paper, which may be used with the greatest freedom, as the glass is held very firmly by the damar varnish, another coat of which is applied by means of the turn-table, and the slide is completed. It would no doubt be more secure if finished with a few coats of gold-size. This process can only be used by those who are somewhat expert, as, should the first attempt fail, the cover cannot be removed and the process repeated. It is a very expeditious mode of mounting, and is likely, in some cases, to prove of great value. Mr. White states that he has had slides mounted for two years which are still perfectly sound and free from air-bubbles. The solution of damar may also be used as a very efficient substitute for the mixture of balsam and benzol. It is, like most varnishes, rather troublesome to make, as, owing to the impurities usually contained in the gum, the varnish requires straining; a somewhat difficult matter with so volatile a solvent as benzol.

(To be continued.)

VOLUMETRIC SOLUTIONS FROM WHICH THE PERCENTAGES MAY BE READ OFF IN THE NUMBER OF VOLUMES REQUIRED.

By WATSON SMITH, F.C.S.

The great advantage to commercial analysts of a method of constructing volumetric solutions from which the percentages may be read off in the number of volumes of such solutions required, or ascertained by a very simple calculation which can be mentally performed with ease, is, I think, palpable. The following is an outline, with examples of the methods of calculation required in titrating these solutions:—

For the sake of brevity, let x = weight of body taken, in which it is required to find the percentage of l; let n = number of volumes of solution required, and *p.c.* stand for percentage.

1st. Solutions from which the *p.c.* may be read off directly, or *p.c.* = n.

The solution is so made that the weight of l, to which each 100 volumes is equivalent, = x; or, in other words, the solution is so made that 100 vols. thereof shall just be equivalent to the amount of l in the weight, x, of the body, supposing it to contain 100 *p.c.* of l.

From the foregoing, it will be seen that, for each solution, x must be a constant weight, in order that the percentages may be obtained in each special manner.

Now, by way of verification, let $x = 10$.

a. Then each volume of solution must be equivalent to 0·1 l or 100 vols. = 10 l.

And, say, 55 vols. of solution have been required in an experiment, then the body contains $\frac{55 \times 0{\cdot}1 \times 100}{10} = 55$ *p.c.* of l.

β. Let $x = 4{\cdot}4$. Each volume of solution must = 0·044 l (100 vols. = 4·4 l); and, say 55 vols. of solution have been required, the body contains $\frac{55 \times 0{\cdot}044 \times 100}{4{\cdot}4} = 55$ *p.c.* of l.

As practical examples, take the following:—

a. It is required that the *p.c.* of NH_3 in a sample of ammonium sulphate be ascertained. Let 5 grms. = x (see Chemical News, Notes and Queries, vol. xx., p. 168); then the acid solution (say hydrochloric) must be made so that each c.c. is equivalent to 0·05 grm. of NH_3 = 0·091 grm. Na_2O.

This is done by weighing out $\frac{106 \times 2{\cdot}5}{132} = 2{\cdot}008$ grms. of sodic carbonate (pure and freshly-ignited), and making the acid so that 50 c.c. thereof are just sufficient to neutralise this 2·008 grms.

A *sodic-carbonate* solution must now be made, exactly equivalent to the acid solution; *i.e.*, 100 c.c. must contain $\frac{5 \times 106}{132} = 4{\cdot}015$ grms. of Na_2CO_3, or 40·15 grms. per litre. Therefore, 40·15 grms. of pure freshly-ignited sodic-car-

bonate must be weighed out, dissolved in pure distilled water, and diluted to 1 litre.

Now, supposing the NH_3 has been distilled off, from the weight of sulphate taken, into 24 c.c. of the HCl solution, and 3·5 c.c. of sodic carbonate solution have been required to neutralise the excess of HCl, then 24 − 3·5, = 20·5 *p.c.* of NH_3 are contained in the sample of sulphate.

b. Again, a convenient "test acid" for estimating the *p.c.* of soda in samples of sodic carbonates and hydrates may be made as follows:—Dilute a quantity of sulphuric acid with about its own bulk of water, and let stand till cold; then further dilute till a Twaddell's hydrometer marks in it 10½° (which indicates about the sp. gr. of the required acid). 5 grms. of pure freshly-ignited sodic carbonate are now weighed out, and the acid is so adjusted that 58·5 c.c. are just required for neutralisation. (NB. Pure Na_2CO_3 contains 58·5 Na_2O.)

2nd. Solutions of decimal strength, or in which *p.c.* = $n \times 0{\cdot}1$.

Where the reagent from which the volumetric solution is to be made is expensive, and the percentages happen to be low, a more dilute liquor is used, and thus a smaller weight, to represent x, is to be taken. Thus, for example, a convenient silver solution, for the determination of the *p.c.* of NaCl in samples of salt-cake, may be made as follows:—

Let x = 2 grms. Make the nitrate of silver solution of such strength that each c.c. = 0·002 grm. of NaCl—*i.e.*, equivalent to 2 grms. of NaCl per litre of silver solution, or 0·2 grm. of NaCl per 100 c.c. Now 2 grms. of NaCl are equivalent to $\frac{2 \times 170}{58{\cdot}5} = 5{\cdot}81$ grms. of $AgNO_3$; therefore weigh out 5·81 grms. of $AgNO_3$, dissolve in pure distilled water, and dilute to 1 litre.

From the preceding, it is seen that the silver solution is so made that 100 vols. thereof shall be equivalent to the amount of $l \times 0{\cdot}1$ in the weight, x, taken (supposing x to contain 100 per cent of l); so that n vols. being required, *p.c.* = $n \times 0{\cdot}1$.

3rd. Solutions of half strength are, also, often useful where the *p.c.* of l is usually very large, and but a small quantity of the body can be conveniently taken (to represent x), for various reasons. In this case *p.c.* = $n \times 0{\cdot}5$.

For a solution of the above strength, 100 vols. of such solution must be equivalent to the amount, $l \times 0{\cdot}5$, in the weight, x, taken (supposing x to contain 100 *p.c.* of l); so that if x = 1 grm., and n = 30 c.c. $30 \times 0{\cdot}5$, or $\frac{30}{2}$ = 15 *p.c.* of l, are contained in the body experimented upon.

Of course, by varying the weight, x, in a particular manner, the same solution may be actually altered from decimal to half strength, or from half to full strength, &c.; thus, from decimal to half strength, take 1-5th x; from half strength to full strength, take ½ x; and from decimal to full strength, take 1-10th x.

The burette, which is used for titrating each solution, should be always used for that particular solution, as burettes which are graduated to hold equal volumes are very often found erroneous.

ECLIPSE OBSERVATIONS.

AMONG the various observations made at the last eclipse, none exceed in interest those of Professor C. A. Young, of Dartmouth College, Hanover, New Hampshire. We quote from the *Journal of the Franklin Institute* an abstract of this gentleman's report:—

The observer was a member of the party under the direction of Professor J. H. C. Coffin, of the Nautical Almanac Office, stationed at Burlington, Iowa.

The instrument employed was a spectroscope with 5 prisms of 45° each, having faces 2¼ by 3¼ inches; the collimator and telescope had apertures of 2¼ inches, with a focal length of 17. These were connected with a "comet seeker" of 4 in. aperture and 30 in. focus, used with an eye-piece, and giving an image of the sun, 2¼ inches in diameter, on the slit of the spectroscope. A graduated screen at the slit determined positions of points on the sun's limb, and a wire micrometer measured the positions of spectrum lines. The whole was mounted equatorially with slow motion screws.

Protuberances were noted before the eclipse at + 85° to 100°, large and not very bright; at + 146°, small and bright. The photographs show another at 155°, which escaped notice; also at − 70° to 80° low, but pretty bright; and at − 130°, very large and bright, the principal one. Angles are reckoned on the sun's limb from the North point, + towards the East, − towards the West.

The first contact was observed by watching the gradual shortening and final extinction of the bright line, C, in the spectrum of the prominence, which happened to be at the point of contact. The moon's approach was perceived full thirty seconds before its actual appulse; the observation was perfectly easy, and the time determined is certainly to be relied on within half a second, and probably much less. The presence of a prominence at the point of contact is not essential to the success of the method, as there is everywhere on the sun's limb sufficient depth of chromosphere to answer the purpose.

It is proposed to apply the spectroscope to observations both of the external and internal contacts at the next transit of Venus.

During the totality, the following nine bright lines were observed in the spectrum, viz., C dazzling in brilliance; 1017·5 (near D, the numbers refer to Kirchhoff's scale), very bright, but not equal to C; 1250±20, very faint, position only estimated; 1350±20, like the preceding; 1474 (a little below E) conspicuous, but not more than half as bright as 1017·5; F, next to C in brightness; 2602±2, a little fainter than 1474, position determined by micrometrical reference to the next; 2796, a little below G, the well-known H.γ line in brightness between 1017·5 and 1474; and finally H, or Hδ, somewhat brighter than 1474. B was not seen, it is supposed on account of a mistake in carrying that portion of the spectrum through the field while there was no prominence on the slit.

The line 1474 was recognised as belonging to the spectrum of corona, in the first place, by its extending clear across the spectrum, while 1017 did not, and then by its remaining visible when the slit was moved away from the protuberance, while the other lines (C and 1017) disappeared. The impression of the observer is that faint lines 1250 and 1350 behaved in the same manner; but his recollection as to this point is not very certain.

These three lines, 1250, 1350, and 1474, coincide far within the probable errors of observation with three lines observed by Professor Winlock in the spectrum of the Aurora Borealis. The two first are not accurately enough determined, in position, to allow much stress to be put upon any apparent coincidences on their part, but the last is perfectly well known, and its exact agreement throughout with one of the fainter lines of the Aurora, when combined with the general appearance of the Corona and other considerations, give a good deal of probability to the conjecture that our Aurora Borealis and the Solar Corona are identical phenomena.

* A careful examination of the photographs of the prominences on the eastern limb of the sun, upon which the slit of the spectroscope was directed during the first half of totality, somewhat diminishes my confidence in the conclusion of the text, as to the nature of these three lines. I think it absolutely certain that they do not belong to the spectrum of the brilliant portion of the prominences; but the photograph shows, in addition, an extensive nebulosity surrounding the nuclei with a pretty definite boundary of its own; this nebulosity is best seen in No. 2 of the totality pictures taken at Burlington. Now, it is possible that these lines may belong to this nebulosity, and not to the corona proper; for I cannot recall, with certainty, whether the 1474 line retained its brilliance at any considerable distance from the prominences. My impression is that it did, and that the text is correct, but do not wish to be too positive. The eclipse of December, 1870, will decide, of course.

The line 1474 is given by both Kirchhoff and Angström (not by Huggins, who, however, omits many faint lines), as belonging to the iron spectrum, and this suggests the inquiry whether we are to admit the existence of iron in the auroral heights of our atmosphere, or are to account for this line in the iron spectrum by some unknown substance of gaseous nature.

The corona showed, also, a faint continuous spectrum without any trace of dark lines. The light of this faint spectrum, tested by a tourmaline held in the hand next the eye, was strongly polarised in a plane passing through the sun's centre. As the direction of the spectroscope slit was nearly radial, it is not impossible that Professor Pickering may be right in explaining this polarisation as caused by the successive refractions through the prisms.

Professor Young's remarks, in his note on the lines in the corona or glow, are curiously in accordance with those of Dr. B. A. Gould, given in the same journal as an extract from a letter to its editor, Professor Henry Morton, who organised and conducted the largest and most successful photographic party during the late eclipse.

Photographs of the Chromosphere.

In a letter just received from Dr. B. A. Gould, we find the following interesting paragraphs, which, with his permission, we extract:—

"An examination of the beautiful photographs made at Burlington and Ottumwa, by the sections of your party in charge of Professors Mayer and Himes, and a comparison of them with my sketches of the corona, have led me to the conviction that the radiance around the moon, in the pictures made during totality, is not the corona at all, but is actually the image of what Lockyer has called the chromosphere.

"This interesting fact is indicated by many different considerations. The directions of maximum radiance do not coincide with those of the great beams of the corona; they remained constant while the latter were variable; there is a diameter, approximately corresponding to the solar axis, near the extremities of which the radiance upon the photographs is a minimum, whereas the coronal beams in these directions were especially marked during a great part of the total obscuration. The coronal beams stood in no apparent relation to the protuberances, whereas the aureole, seen upon the photographs, is most marked in their immediate vicinity. Indeed, the great protuberance, at 230° to 245°, seems to have formed a southern limit to the radiance on the western side, while a sharp northern limit is seen on all the photographs at about 350°, the intermediate arc being thickly studded with protuberances, which the moon displayed at the close of totality. The exquisite masses of flocculent light on the following limb are upon the two sides of that curious prominence at 93°, which at first resembled an ear of corn, as you have said, but which in the latter pictures, after it had been more occulted, and its southern branch thus rendered more conspicuous, was like a pair of antelope horns, to which some observers compared it. Whatever of this aureole is shown upon the photographs, was occulted or displayed by the lunar motion, precisely as the protuberances were. The variations in the form of the corona, on the other hand, did not seem to be dependent in any degree upon the moon's motion.

"The singular and elegant structural indications, in the special aggregations of light on the eastern side, may be of high value in guiding to a farther knowledge of the chromosphere. They are manifest in all the photographs by your parties which I have seen, but are especially marked in those of shortest exposure, such as the first one at Ottumwa. In some of the later views they may be detected on the other side of the sun, though less distinct. But the very irregular and jagged outline of the chromosphere, as described by Janssen and Lockyer, is exhibited in perfection.

"This happy result is clearly attributable to the relative shortness of the time of exposure by which the highly photographic rays of the chromosphere have depicted themselves, without obliteration by the mass of coronal light which veiled them from the eye. Let us hope that at the next total eclipse some impressions may be taken with an exposure not exceeding a single second, as you have suggested. The inference seems warrantable that in this way, better than in any other, the internal structure of the protuberances may be exhibited, though other phenomena may fail to record themselves.

"You will observe that some of the brighter, petal-like flocculi of light have produced apparent indentations in the moon's limb at their base, like those at the basis of the protuberances. These indentations are evidently due to specular reflection from the moon's surface, as I stated to the American Association at Salem last month. Had any doubt existed in my mind previously it would have been removed by an inspection of the photographs.

"I shall send the substance of these remarks to Professor Coffin, as a sort of postscript to my report, which contains only the results of personal observation at the time."

SIMPLE APPARATUS
FOR
RAPID VAPOURISATION AT LIMITED HEAT,
UNDER REDUCED PRESSURE, WITHOUT USE OF A PUMP.

By A. B. PRESCOTT,
Assistant Professor of Chemistry, &c., University of Michigan, U.S.

The pump is not always at hand; its use is forbidden for transmission of corrosive vapours; and, moreover, the removal of liquids, in form of vapour, against the weight of the air by muscular power is liable to "exhaust" the operator more effectively than it does the material. I desire to ask attention to some uses of ordinary distilling apparatus, for the production and maintenance of approximate vacuum over liquids during their vapourisation, in cases where the heat of 120° to 150° F. may be applied.

It is necessary that the distilling apparatus be made capable of air-tight closure, and that the air be removed from it to begin with. Then the degree of exhaustion in the apparatus is in direct ratio to the rapidity of condensation of the vapour produced. And the rapidity of condensation is only limited by the degree and extent of refrigeration employed, with a given extent of evaporating surface at a stated temperature. The air in the apparatus, to begin with, may be expelled through a suitable aperture by steam, which may be generated in the "receiver" of the apparatus or in an attachment thereto.

Take two round-bottomed glass flasks, the one having a capacity four to eight times greater than the other. Adjust the smaller upon a water-bath, the larger, at 10 or 15 inches distance from the other, over a sink or large basin, and connect the two with glass tubing and perforated caoutchouc stoppers, so that the connecting-tube shall incline slightly downward from its bend close to the stopper of the small flask. The stopper of the small flask is also to have a second perforation, in which is fitted a straight glass tube, 2 or 3 inches long, its lower end placed even with the lower end of the stopper. The upper end of this tube is very slightly drawn out for ¼ of and inch, and snugly fitted with 1½ inches of firm rubber tubing, the upper ½ inch of which is closed with a piece of glass-rod of same diameter as the body of the tube.

Now put an ounce or two of water in the large flask, and the material to be evaporated in the small flask; close the stoppers perfectly, by turning the flasks under

them, and leave open the straight tube. Apply, by the water-bath, the limited degree of heat until it is imparted to the contents of the small flask; then move a lamp under the large flask until the water in it has boiled briskly and the steam therefrom has escaped continuously from the straight tube for some minutes. Now close tightly the straight tube with its caoutchouc cap, at the same time removing the lamp from the large flask. When the latter has cooled somewhat, wrap it smoothly with linen netting or gauze, and lead upon it a minute stream of cold water, controlling the same as required. The liquid in the small flask boils briskly (if aqueous, boiling at 120° to 150° F.), and the refrigeration is governed to prevent too violent ebullition, lest liquid be thrown into the connecting-tube: the degree of applied heat is governed to the same end.

An ordinary glass retort may be substituted for the small flask as an evaporating vessel, and its tubule may be fitted with a perforated stopper, admitting a thermometer. If there is not room in the stopper (of retort or flask) for both the thermometer and the steam-escape tube, the latter may be dispensed with by adjusting the stopper loose for escape of steam, and pressing it tight when the air is expelled. Flat-bottomed flasks favour equable boiling, but they are liable to collapse.

As a *condenser*, I have used, instead of the large flask, a copper vessel, for more ready application of heat without danger of breaking, and for more efficient refrigeration. This copper receiver (Fig.) is made of conical shape, with rounded bottom, a vertical diameter twice its horizontal diameter, and a neck bent to the angle of about 56° with the vertical axis of the vessel. The diameter of the neck is ¾ of an inch, to receive a retort beak, the joint being covered with a section of caoutchouc tubing. Or it may be fitted with a perforated stopper, to receive the connecting-tube of the flask when evaporation is conducted in the latter.

With linen netting to spread the water over the free surface of the condensers, the evaporation therefrom refrigerates with a comparatively small supply of water. Using a copper condenser of the above-described shape, a vertical diameter of 12 inches, and capacity of 6 pints, attached to an 8-ounce glass retort containing distillation promoters, I have vapourised 4 fluid ounces of water in sixteen minutes at the constant temperature of 128° F. By ordinary care in the expulsion of air and closure of the apparatus, exhaustion can be invariably secured, fixing the water boiling-point at or below 130° F.; that is, atmospheric pressure equal to at least 25 inches of mercury may be removed and sustained by availing ourselves of the displacing effect of steam, and the contraction of condensing vapour, in very simple apparatus.

Notwithstanding the illustrations of vacuum by condensation which abound upon the physical lecture-table, I do not know whether the devices suggested in this note have been tried or proposed for small chemical operations by anyone else. I have recommended them to students, and we have found them satisfactory for various analytical, experimental, and pharmaceutical operations. We have employed them chiefly in such evaporations as are performed for the residue only, or, at least, not for quantitative recovery of the distillate, in various evaporations of quantitative analysis, in the elimination of non-volatile alkaloids, in determining the organic matter in water, and in preparing fluid extracts. To evaporate at ordinary temperatures by hand-pump exhaustion is especially irksome in those cases when application of 125° to 150° F. is unobjectionable. And to connect a vessel under which heat may be applied with the air-pump involves quite as much labour as the arrangement of apparatus for exhaustion by condensation.

NOTICES OF BOOKS.

Exercises in Practical Chemistry. By A. VERNON HARCOURT, M.A., F.R.S., and H. G. MADAN, M.A. Series I., *Qualitative Exercises.* Oxford: Clarendon Press. 1869. 335 pages.

THIS joint work of Messrs. Harcourt and Madan is the last volume which has appeared in the very useful "Clarendon Press Series" of Messrs. Macmillan and Co.; and it forms the first half of a work which is to include quantitative analysis. The object of the work "is to furnish a systematic course of study to those who are beginning to learn chemistry practically;" and, with this in view, the authors have detailed, with much care and precision, the nature of, and the mode of manipulation with, all the more general apparatus, and have given in the Appendix suggestions for the construction of the simpler apparatus.

At the outset, we notice, under the head of "Memoranda," a series of ten aphorisms, embodying, in very terse language, rules for the attainment of the exactness and precision of action, and of the attitude of mind which must accompany chemical work. Such are:—

1. "Be orderly and neat in manipulation. Cleanliness stands at the head of the chemist's scale of virtues. All messes must be cleared away with the zeal of a sanitary inspector.

2. "Do not begin work in a hurry.

3. "Be economical of materials.

6. "Do not think merely of what will *do*, but what is *best*, of the means at your disposal.

10. "Finally, do not look upon chemistry as a mere amusement—as a means of getting up a few explosions, creating a few unsavoury smells, producing a few striking changes of colour. Chemistry is worthy of better treatment. It is no longer a 'black art,' but a refined science, and should be thoughtfully and reverently studied."

After the "memoranda," we have a list of the apparatus, and of the substances required for the work described. The illustrations of apparatus are, for the most part, drawn on the block direct from photographs taken by one of the authors. We do not notice the introduction of any new or modified form of apparatus; and that which is described is (as it should be) of the very simplest and cheapest description. Part I. is devoted to "Experiments on the Preparation and Properties of Substances," and this is commenced by an account of different operations, such as—"Fusion and Granulation;" "Glass-working;" "Solution, Evaporation, and Crystallisation;" "Precipitation and Filtration;" "Distillation;" Use of the Pneumatic Trough." Each of these is described with the utmost detail; for instance, more than two pages are devoted to the method of boring a cork, and more than three to the use of the pneumatic trough.

Section 2 treats of the "Preparation and Examination of Gases;" and each *exercise* is conveniently headed by a list of the apparatus and materials required for the preparation of the particular gas about to be described, even down to "cedar matches," and "a jug of water." We do not think that the list of experiments is at all sufficient; nor does there seem to be any effort to introduce new or modified effects. In the experiments in connection with oxygen, the burning of sodium in that gas is not mentioned; yet this is surely an experiment of the utmost importance, for it behoves the teacher to show the inappropriateness of the name oxygen, inasmuch as, by its combination with substances, are produced, not alone acid compounds, but also some which are neutral and alkaline. Again, the burning of naphthaline in oxygen is a very notable experiment; as, also, the burning of thallium, zinc, and aluminium. Hydrogen, nitrogen, and the protoxide and dioxide of nitrogen are next described; and an account of the collection of gases by displacement heralds "Carbon Dioxide," in the account of which we

are glad to notice the capital experiment of burning magnesium in a bottle of that gas, which is a far easier plan than the old arrangement of a bulb-tube and red-hot potassium. To separate the black flakes of carbon from the white flakes of magnesia, the bottle is to be rinsed out, and hydrochloric acid added to dissolve the magnesia. In order, follow—"Carbon Protoxide," "Ammonia," "Hydrogen Chloride," "Chlorine," "Ethylene," and "Sulphur Dioxide." Remembering to how large an extent the work before us will be used in schools, and the usual recklessness of boys, we think it behoves the authors, in the next edition, to add special precautions in regard to explosive substances. For instance, we do not think that nearly enough has been said about the danger of exploding ethylene with oxygen gas, from the careless management of which experiment a really serious accident might without difficulty arise.

Section 3 treats of the "Preparation of Reagents used in the Laboratory." The preparation of solutions of hydrogen sulphide, of chlorine, of chloride of tin, and of "Hydrogen and Silicon Fluoride," is here described. Then follows an extremely useful chapter on the "Preparation of Normal Solutions of Reagents," in which no less than thirty-seven solutions are described.

Section 4 treats of "Experiments with the Mouth Blowpipe;" and Part 1 is concluded by Section 5, wherein is detailed an "Examination of the Properties of the Principal Radicles and their Salts." Nearly one-third of the book is devoted to this subject; and explicit accounts are given of the properties and mode of examination of all the substances in most general use in the laboratory. The following may be taken as an example:—

"Place a bit of magnesium-ribbon, about 25 c.m. in length, in a test-tube, and pour on it some dilute hydrogen sulphate. Hydrogen gas will be evolved with effervescence, and the metal will gradually dissolve. When the action has ceased, pour off the liquid into a small porcelain dish, and evaporate it down until it begins to crystallise. Long prismatic crystals of magnesium sulphate (Epsom salts) will be deposited in abundance as the solution cools; these should be re-dissolved in about 20 c.c. of water, and separate portions of the solution tested as follows:—

(*a*) "To a portion, add a drop or two of solution of ammonium sulphide. No precipitate will be formed, since magnesium sulphide, unlike zinc sulphide, is soluble in water."

The other usual tests follow—sodium carbonate, ammonium carbonate, ammonia and ammonium chloride, and the blowpipe test with cobalt.

Part 2 treats of the "Qualitative Analysis of Single Salts," and is divided into six sections, of which the first explains the general nature of the analytical course; the second, the "Preliminary Examination of the Substance;" the third, the "Examination of the Solution of a Single Salt for a Metal;" the fourth, the "Examination of the Solution of a Single Salt for Non-metallic Radicle;" the fifth, the "Examination of an Insoluble Substance;" and the last, an "Example of the Analysis of a Single Salt." A general grouping of substances is given in the first section, together with a table showing the distribution of the principal metals into groups for the purposes of separation. The preliminary examination is discussed under thirty-one separate heads, and is very clear and precise. The whole subject of Part 2 is divided into seventy-four minor heads, and these are distinguished by bold and black figures placed near the margin. The extent to which printers' type can indicate a desired difference by its own difference of form is surely well shown in this work; for, in a single page, we observe no less than *nine* different kinds of type.

The work is concluded by six short appendices, whereof the first contains "Suggestions for the Construction of Chemical Apparatus;" and here we find such proposals as the conversion of a biscuit-tin into a pneumatic trough, of a door-handle into an Argand burner, and of a tobacco-pipe into a deflagrating spoon. Without doubt, it may be well sometimes for the student to exercise his ingenuity in this way; but, when we remember the extreme cheapness of all the more ordinary chemical apparatus, we do think a great deal of time is often wasted in the attempt to construct that which, after all, is but a clumsy and short-lived piece of apparatus. Appendix B discusses the recovery of gold, platinum, and silver from their residues. Appendix C contains a very useful table of the solubility of a number of salts, on the authority of Storer's "Dictionary of Solubilities." Appendix D contains "Tables of Weights and Measures." Appendix E treats of "Thermometric Scales." And, finally, Appendix F discusses the nature of chemical symbols, which are very sparingly used throughout the work. The index is short, but is, perhaps, sufficiently long for a book which, to a certain extent, constitutes its own index.

Regarding the book as a whole, it may be said to contain a large and varied amount of information; the matter is condensed as much as possible, although considerable minuteness of detail is frequently apparent. We confess that the arrangement often appears to us to be complex, and we do not grasp the design which the authors had in view in certain of their modes of arrangement. Indeed, every new work on Chemistry appears to us more complex than that which preceded it; Bloxam's "Laboratory Practice" is surely a less complex (but in all fairness, be it remembered, also a less comprehensive) work than that of Messrs. Harcourt and Madan; while, to our mind, the least complex work of all is "Bowman's "Practical Chemistry." It will be borne in mind that we speak here solely of arrangement of matter and simplicity of style. Perhaps we are too conservative in all this; perhaps we like too much *stare super antiquas vias*, but, truly, we think that much of the chemical literature of the period is characterised by unnecessary complexity and obscurity. At the same time it is undeniable that Chemistry itself is advancing in the same direction, and so long as this continues to be the case, we cannot expect to have a different literature. The importance of an extreme simplicity in the mode of teaching a new and difficult science to boys cannot be exaggerated. A boy with some glimmer of a taste for science will, if he meet with a rebuff at the outset, probably abandon the study altogether. The questions which boys ask after hearing a lecture indicate how they often unwittingly create difficulties, and in the abstruse branches of analysis these difficulties must more frequently arise. Let it be remembered, however, that Messrs. Harcourt and Madan have had much experience in science teaching, and we may feel very sure that they have embodied the sum and substance of that experience in the work before us. They are both well qualified to write on the subject, and they have done justice to it. Their work appears very opportunely, for now, more than ever, is the establishment of school laboratories and science classes receiving the attention of all who are interested in the educational progress of this country, and we are well assured that the work we have been considering will be much used both in the higher classes of our schools and in our universities.

The City of London Gas Act.—We have received from Dr. Letheby his report on the results of the daily testings of the gas supplied to the City during the quarter which ended on the 30th day of September last, from which we find that the maximum illuminating power of the Cannel gas supplied by the City of London Gas Light and Coke Company has been equal to 27·50 standard sperm candles, the minimum to 19·50 candles, and the average to 24·58. The gas supplied by the three companies has been free from sulphuretted hydrogen, but the proportions of sulphur have fluctuated to a large extent. Ammonia has also been found in the gas supplied by the Chartered Company. The use of Sugg's New London Argand Burner of 24 holes shows an increase of illuminating power of sixteen per cent.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

In accordance with the generally expressed wishes of our friends and readers, we have effected arrangements to enable us to give, under the above heading, notices of EVERY CHEMICAL PAPER IN THE WORLD, *as soon as possible after publication. Whenever possible, these notices will appear in the form of carefully prepared, although necessarily brief, abstracts; as respects papers either too long or too abstruse to render condensation possible, their titles will be chronicled; and in all cases accurate reference will be made to the original publication. The two half-yearly volumes of the* CHEMICAL NEWS, *with their copious indices, will therefore be equivalent to an English edition of the "Jahresberichte," with the additional advantage of keeping the readers week by week on a level with the latest advances of science.*

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, October 25, 1869.

The following original papers and memoirs bearing upon chemistry and physical science are contained in this number :—

Remarks on the Communications made by MM. Vergnette, Lamotte, and Thenard.—M. Pasteur.—The author of this lengthy and criticising review condemns, in terms fortunately not frequently heard in the Mazarin Palace, the processes of the preservation of wine by heating it. The paper is too lengthy to admit of abstraction, and is, moreover, only of interest to wine-growing countries.

Fundamental Equations of the Mechanical Theory of Heat.—M. Reech.—A purely mathematical paper.

Illumination of Transparent Substances by means of Polarised Light.—M. Lallemand. In order to see the illumination of any fluid, water, for instance, it is poured into a glass tube, which is closed at both ends by means of pieces of plate glass; the tube is then placed in a dark chamber in a horizontal position, and a ray of polarised light is made to shine upon the tube, which, when looked at sideways, will exhibit a vivid glimmering; but, seen in any other direction, the tube remains dark. Hence, it follows that the propagation of the light takes place in the direction of the plane of polarisation; and it also follows that the vibrations of the waves of the ether take place in the perpendicular direction. When, instead of water, any other fluid is taken which is endowed with rotatory power—a solution of sugar, for instance—a very beautiful chromatic effect is displayed; the colours of the spectrum will be seen distributed in an elliptical shape. Cylinders of solid glass, submitted to the same experiment, exhibit somewhat similar phenomena, but less conspicuously than fluids.

Calorific Rays Emitted by the Moon.—M. Marié-Davy.—The author retracts his former negative statements on this subject, and now proves that, by another, and differently-conducted set of experiments, he found that the moon emits calorific rays in abundance. The secretary read, also, a memoir on this subject, by M. Volpicelli, who, quoting the observations of more ancient and modern *savants*, comes to the conclusion, also, by his own observations, that the moon emits heat.

Bronzing of Copper.—M. Zalewski.—When objects made of copper are immersed in molten sulphur wherein lamp-black is kept suspended, the objects so treated obtain the appearance of bronze, and can be polished without losing that aspect.

Influence which Divers Luminous Rays Exert upon the Decomposition of Carbonic Acid, and the Evaporation of Water from the Leaves of Plants.—M. Dehérain.—The author, having extended his experiments on this subject, now states that all the luminous rays are not equally active in the decomposition of carbonic acid; that, even when the intensity is the same, the yellow and red rays act more favourably than the blue and violet rays; that the relation between decomposition and evaporation remains unaltered.

Preparation of Oxygen.—M. Delaurier.—The author states that, when manganate of lime is heated, oxygen is abundantly given off, and that by means of this salt it may be made very economically.

Metrical Weights and Measures.—M. Jacobi writes to the effect that the Royal Prussian Academy of Sciences is favourably disposed towards the proposal to establish an international committee for weights and measures.

Testamentary Disposition by M. Lacaze.—The perpetual secretary, M. Dumas, announces that the late M. Lacaze has bequeathed to the Academy a sum of 10,000 francs (£400), the interest of which is to be applied, bi-annually to the distribution of prizes for chemistry, natural philosophy, and physiology.

The Journal of the Franklin Institute, September, 1869.

This number contains the following original papers and items :—

Gas Blasting.—While an excavation for a gas-holder tank was being made at Oswego, an old well had been pumped out and then filled up, after leaving an aperture beneath. Into this space a limited quantity of gas was introduced from the gas pipe, sufficient to form an explosive compound with the air in the covered well; this mixture being exploded by suitable means, caused a general upheaving of the surrounding earth, loosening the soil, and making digging easier.

Analysis of Hathorn Spring Water.—Dr. Chandler.—Grains to the gallon—Chloride of Sodium, 509·968; chloride of potassium, 9·597; bromide of sodium, 1·534; iodide of sodium, 0·198; fluoride of calcium, a trace; bicarbonate of lithia, 11·447; bicarbonate of soda, 4·288; bicarbonate of magnesia, 176·463; bicarbonate of lime, 170·646; bicarbonate of strontia, a trace; bicarbonate of lime, 1·737; bicarbonate of iron, 1·128; phosphate of soda, 0·006; biborate of soda, a trace; alumina, 0·131; silica, 1·200; organic matter, a trace; total solid constituents, 888·403 grains; carbonic acid gas in one gallon, 375·747 cubic inches; specific gravity, 1·009.

Various Processes for Preserving Timber.—Dr. Ott.—From this paper, which is to be continued, we learn that the first attempts in this direction were made by the German chemist Glauber, and consisted in first charring the surface of the timber, then coating it with Stockholm tar, and immersing it in crude acetic or more properly pyroligneous acid. The author then reviews at length the various methods applied for the preservation of timber, treating of injection with brine, or salting timber, which is not of much use unless, indeed, the salt could be made to penetrate through the very heart. Speaking of Mr. Beer's process, that is to say the treatment of wood in a boiling solution of borax in water, the author observes that beside the ready solubility of borax in water (one part in twelve of cold water), borax, like all alkaline salts, has the property of dissolving, or at least attacking, the so-called incrustating matter of the wood, upon which its strength, solidity, and toughness greatly depend; moreover, borax also dissolves the resin which is therefore eliminated from the wood, and in regard to its (borax) claimed superiority in withdrawing the putrefiable substances, it may be stated that not less than 14 per cent of the original amount of albumen have been retained in saw-dust, after boiling it several times, and each time for hours with a saturated solution of borax.

Cosmos, October 23, 1869.

Extracts from Vegetables.—M. Berjot.—This gentleman has applied to the vegetables in ordinary use for culinary and domestic purposes the process long since very successfully carried out for vegetables to be used in pharmacy, viz., of expressing by strong hydraulic pressure the juices of such vegetables, and concentrating the same by evaporation *in vacuo*, and preparing extracts thereof suitable for making soups and sauces, 1 gramme of these extracts being sufficient to convert 1 litre of bouillon into a good soup.

Porte-plume-encrier Vélocigraphe.—Dr. Poznanski.—Under this title is described at great length, accompanied by a woodcut, an instrument which, if what is stated about it is correct, will, in a very short time, be greatly in demand by all who have much writing to do. The instrument is a combination of pen-holder, pen, and ink reservoir, and the ink flows into the pen by means of a self-acting valve and piston, as long as the writer requires it; we cannot give more details without re-producing the cut.

Estimation of Urea.—Dr. Byasson.—Take 50 c.c. of the urine to be tested from the urine in a flask, and next add 25 c.c. of baryta water, and shake the mixture, filter off the precipitate, the filtrate from which should be alkaline; take 10 or 20 c.c. of this filtrate, and pour it in a vessel suitable for precipitation, and place the vessel on a sheet of white paper; then add from a graduated burette a mercurial solution (made by dissolving 36 grammes of red oxide of mercury in 50 grammes of nitric acid diluted with as much water; this dissolution is aided by heat and carried on until, by evaporation, red fumes are beginning to be given off, when the saline mass is dissolved in 1 litre of distilled water), keeping the fluid well stirred. From time to time small quantities of a solution of caustic potassa of 25 grammes to the litre are added; by this proceeding a yellow precipitate is formed. This first assay is only approximative, and should be followed by at least two other similar operations. Every c.c. of the mercurial liquid applied represents 0·005 gramme of urea; the mercurial solution is controlled by means of a urea solution made by dissolving 20 grammes of crystallised urea in 1 litre of distilled water.

Zeitschrift für Chemie von Beilstein, No. 19, 1869.

This number contains the following original papers :—

New Method for the Synthetical Preparation of Salicylic Acid and its Homologues.—M. Vogt.—The author says—Some few months ago, M. Oppenheim and I proved that chloride of phenyl is not readily acted upon by fusing caustic potassa, unless that chloride is converted into the corresponding sulpho-acid. While the writer was engaged in experiments with chlorinated toluol and xylol, expecting to obtain orcine and β orcine, the result was the formation of salicylic and cresotinic acid. Chlorinated toluol was mixed with fuming sulphuric acid, and afterwards submitted to heat; as soon as the chlorinated compound was dissolved, the mixture was diluted with water, and baryta solution was added, until a precipitate ceased to appear. The liquid was next filtered, and neutralised with a solution of carbonate of potassa; in this manner a salt, $C_7H_5ClSO_3K$, was obtained in pearly plates. This compound was fused with caustic potassa, and, after a lengthy purifying treatment, first with water, next hydrochloric acid in excess, then ether, and again saturation with carbonate of potassa, and decomposition, again, of the saline mass by excess of an acid, salicylic acid was obtained, in small quantity, but sufficient to test its most prominent features. Bromated toluol,

treated in the same manner, yields the same result. Chlorinated xylol, submitted to the same treatment, yields cresotinic acid, a solid substance which crystallises in elongated prisms, fuses at 148°, difficultly soluble in water, and yields, with chloride of iron, a violet tinge.

Action of Deutoxide of Nitrogen upon Terpen.—M. Bunge.—The author says—Some thirty years ago, M. Cahours published a paper wherein it was stated that deutoxide of nitrogen combines with the terpen of essential oil of feuchel, yielding a substance, $C_{13}H_{21}(NO)_4$, which, consequently, is a nitroso hydrocarbon. These researches of the last-named author have been repeated by the author of this paper, with the following results:—(1) Pure deutoxide of nitrogen does not combine with the terpen of essential oil of feuchel, and is hardly even absorbed by it; (2) when the deutoxide of nitrogen is brought into contact with the aforesaid terpen, air being at the same time admitted, the compound described by Cahours is formed; (3) pure hyponitric acid, prepared from nitrate of lead free from chlorine, is plentifully absorbed by the terpen alluded to, but the result is not the formation of a crystalline substance; (4) when the terpen is mixed with an aqueous solution of nitrite of potassa, to which some acetic acid is added, the terpen is thereby converted into a crystalline mass, which, although identical with that described by M. Cahours, differs from it in composition, its formula being $C_{10}H_{18}(N_2O_4)$. Ordinary oil of turpentine (purified, of course), and the terpen from Copaiva balsam, do not yield, when treated as described, crystalline compounds. When the nitrate of lead, employed for the evolution of hyponitric acid, contains chlorine, or if, purposely, chloride of lead is added to the nitrate, and the gas thus obtained be passed through the terpen of essential of feuchel, this fluid soon becomes turbid, and the result is the formation of a substance insoluble in water and hardly soluble in either absolute alcohol or ether; this compound is expressed by the formula $C_{10}H_{14}NO_3Cl$. The terpen of copaiva balsam yields an analogous compound.

Formation of Green Sulphide of Manganese by the Wet Way.—M. Muck.—When the salmon-coloured sulphide of manganese is submitted to heat while yet in moist state, it becomes green. The author distinctly states that the green sulphide alluded to is not identical with that obtained by the dry way. After quoting several observations of the same phenomenon recorded by other scientific men, the author says—The salmon-coloured sulphide of manganese, when seen under the microscope with a magnifying power of from 200 to 300 diameters, is observed to be a completely amorphous substance; the green sulphide, however, exhibits, under the same conditions, greenish coloured transparent quadratic tables. The preparations of manganese applied for the purposes of experiments, are perfectly pure, and quite free from any other metals precipitable by hydrosulphuret of ammonium. The results of a series of researches on this subject are, that, when an excess of hydrosulphuret of ammonium is applied as precipitant:—1. Very dilute and cold solutions of the chloride and sulphate of manganese yield a salmon-coloured MnS, which, even when kept for several weeks, does not exhibit the least tendency to become green coloured. 2. The same solutions, when precipitated while hot, yield flocculent precipitates, which are bright green-coloured; the solution of the sulphate yields a precipitate akin in colour to the hydrated oxide of chromium. 3. When the same solutions are quite concentrated, the precipitates formed are, at first, salmon-coloured; but, after a short time, and even without the application of heat, the precipitates, while shrinking enormously, and becoming pulverulent, get green-coloured. When a large proportion of a solution of chloride of ammonium was added to the solutions of the salts of manganese just alluded to, previous to adding the precipitant, a nearly blackish green, very dense MnS was thrown down. The following salts of manganese, in solid state, behave towards hydrosulphuret of ammonium in the manner thereby respectively expressed:—The chloride is rapidly converted into a green sulphide, even at the ordinary temperature of the air; the sulphate is more slowly acted upon, but the result is the same; the nitrate, solid as well as solution, is only partly converted into a green sulphide; the phosphate and oxalate yield, rapidly, a green sulphide; the carbonate never yields a green sulphide, but always the salmon-coloured. A concentrated solution of the chloride of manganese yields, on being precipitated by the hydrosulphuret of ammonium only, then, a green sulphide of manganese when the precipitant is in excess and all the metal thrown down; the green sulphide yielded, on careful analysis, by means of drying in a current of dry sulphuretted hydrogen gas, 7·43 per cent of water. When, instead of hydrosulphuret of ammonium, the various soluble sulphides of potassium or sodium are applied as precipitants, the author never obtained a green sulphide of manganese under any conditions.

Conditions under which the Sulpho-Carbanilide and some Analogous Substances are Decomposed.—MM. Merz and Weith.—The subject treated of in this lengthy essay may be summarised in the following manner:—The authors proved that nascent hydrogen has the effect of desulphurising sulphocarbanilide; but, instead of obtaining, as they expected, methylendianiline, other products appeared. This phenomenon they attributed to the presence of acid, and, therefore, they repeated experiments formerly made, and applied perfectly neutral solutions; but this precaution, notwithstanding the sulpho-carbanilide, was decomposed as before. The paper contains, further, a lengthy description of the origin and products of decomposition of a number of complex organic substances, as, for instance, triphenyl-guanidine, sulpho-carbanilamide, tricarbo-hexanilide, and others.

Action of Permanganate of Potassa upon Quinine.—Dr. Kerner.—One part of pure quinine is dissolved in excess of pure nitric or hydrochloric acid; the solution is heated to about 50° or 60°, and there is added to it a concentrated solution of two parts of permanganate of potassa in water at the same temperature, and the liquid well stirred and heated some 15° or 20° higher. The fluid is separated by filtration, from the precipitate of peroxide of manganese, and next evaporated to about one-eighth of the original bulk. The liquid, which should exhibit an alkaline reaction, is next acidified, upon which the new substance, dihydroxyl of quinine, is precipitated; this material will require to be purified from colouring matter by means of a very dilute solution of soda. The purified substance, after having been re-crystallised from its aqueous solution, exhibits a crystalline material, difficultly soluble in cold water and alcohol, and more readily so in these fluids when hot. Its composition is represented by $C_{20}H_{26}N_2O_4$; its formation from quinine may be represented by—

$$C_{20}H_{24}N_2O_2+H_2O+O=C_{20}H_{26}N_2O_4.$$

On Oxytolliden.—MM. Limpricht and Schwanert.—When an ethereal solution of toluylen is treated with bromine, there is formed, besides bromated compounds, a substance, $C_{14}H_{10}O_2$, which the authors call oxytoliden, in pure state exhibiting a solid crystalline substance, fusing at 172°, subliming at a higher temperature, without decomposition, soluble in ether and alcohol, not acted upon by an alcoholic solution of potassa, neither by reducing agents. The authors obtained, by means of the action of chlorides of phosphorus upon this oxytoliden, chloroxytoliden, $C_{14}H_9ClO_2$, a solid substance, fusing at 57°, and soluble in alcohol; trichloroxytoliden, $C_{14}H_7Cl_3O_2$, also a solid substance, fusing at 87°, and readily soluble in warm alcohol; pentachloroxytoliden, $C_{14}H_5Cl_5O_2$, a solid matter, fusing at about 190°, and difficultly soluble in hot alcohol. The structure of oxytoliden is represented by—

$$\begin{matrix} C_6H_4-O-CH \\ \quad\quad\quad\quad | \\ C_6H_4-O-CH \end{matrix}$$

On Thionessal, Tolallylsulphide, Lepiden, and Oxylepiden.—Dr. Dorn.—Thionessal, $C_{28}H_{20}S$, is not readily desulphurised, even by being heated to a feeble red heat along with either iron or copper filings. The heating of thionessal with chloride of phosphorus also fails to effect desulphuration; but there is formed a bichloride of thionessal, $C_{28}H_{18}Cl_2S$, a solid substance, fusing at 219°. Tolallylsulphide resists the action of red-hot copper; but, on being treated with chlorate of potassa and hydrochloric acid, it is readily converted into oxylepiden, and therefore the formula of tolallylsulphide ought to be $C_{28}H_{30}S$. Oxylepiden, $C_{28}H_{20}O_2$, when acted upon by reducing agents, is converted into lepiden, $C_{28}H_{20}O$, which does not, however, give up any more of its oxygen to any reducing agents; and when it is treated with chloride of phosphorus, yields a series of products of substitution, containing chlorine—viz., bichloroxylepiden, $C_{28}H_{18}Cl_2O_2$; bichlorlepiden, $C_{28}H_{18}Cl_2O$; pentachlorlepiden, $C_{28}H_{12}Cl_5O$; hexachlorlepiden, $C_{28}H_{14}Cl_6O$; and octochlorlepiden, $C_{28}H_{12}Cl_8O$. All of these are solid substances.

The Pyromucic Acid Group.—M. Limpricht.—The combinations of this group can, according to this author, be deduced from a hydrocarbon—

$$\begin{matrix} HC=CH \\ | \quad\quad | \\ HC=CH \end{matrix}$$

In order to prove this statement, a series of experiments have been made, which are recorded in this paper. Pyromucic acid in aqueous solution is decomposed by bromine, with evolution of carbonic acid, according to the following formula:—

$$C_5H_4O_3+H_2O+Br_2=C_4H_4O_3+CO_2+2HBr.$$

There are simultaneously formed a bromo substitute, an oily substance, and, under conditions which are not precisely defined, a compound, $C_4H_3BrO_3$, a solid, insoluble in water, alcohol, and ether, and fusing at 84°. Among the products of the complete decomposition of an aqueous solution of pyromucic acid, fumaric acid, $C_4H_4O_4$, occurs; and this acid, treated with sodium amalgam at 180°, yields succinic acid.

Arsenic in the Soda of Commerce.—Dr. Fresenius calls attention to a fact, accidentally discovered by him, that the carbonate of soda (neutral), as met with in crystallised state, and as manufactured at the alkali works, now often contains a very perceptible quantity of arseniate, or arsenite of soda, undoubtedly due to the use of sulphuric acid for converting the common salt into sulphate of soda, which acid contains arsenic, derived from the pyrites of which few are quite free from arsenic, and some of which contain that substance in considerable quantity. The tests applied for the detection of this arsenic were not the most delicate in use for this purpose; and the quantity found, though small, is sufficient to affect the purity of preparations for medicinal and chemical use.

Les Mondes, October 28, 1869.

From this number we abstract the following original communications and papers:—

Electrical Explorator.—M. Trouvé.—Although this subject does not exactly bear upon chemical science, we may call attention here to what is stated in the original. The explorator alluded to is a small instrument destined to detect, by means of electricity (galvanic current), any metallic or other objects, but especially rifle-balls and pieces of shot and shell, which may have penetrated the body or limbs of men and animals. At an Exhibition, recently held at the Hague, of objects relating to army surgery, and the necessary means of taking care of the wounded in battles, Dr. Winkhuijsen, physician to His Majesty the King of the Netherlands, ingeniously introduced, in limbs made of plaster of Paris, different projectiles of iron and lead, and was thus enabled to exhibit the action of this very useful instrument, by the aid of which, even though no open wounds exist, the presence of such projectiles may be readily detected with certainty, and the extraction

proceeded with. Not only metallic, but also stone and wooden objects, which might have penetrated, can be detected.

On Combustion.—M. A. Boilot.—The author's chief conclusion on this subject is, that the distinction between supporters of combustion and combustibles is a pure fiction; there are neither combustibles, nor supporters of combustion, nor, also, any inert substances. In all reactions, each substance brings with it a portion of caloric, and absorbs a certain quantity thereof. Incandescence and heat are, in many cases, principally, if not solely, due to oxygen, but equally so to other bodies under other conditions. Oxygen is not only a supporter of combustion, but it is as much a combustible as the substances which burn in it.

Galvanic Tinning.—M. Maistrasse-Dupré.—The author, it appears, has been commissioned by the French government to apply, by galvanic means, tin upon divers objects which had been made of so-called galvanised iron—that is, iron covered with zinc. To this purpose he applied galvanic elements made of copper and zinc plates, the length of which is 1·20 metres, the width 0·70 metre, placed in a leaden trough, and separated and isolated by means of wooden partitions. The copper sheet was immersed in a mixture of equal parts of acetate of lead and common salt; and the zinc element was placed in weak sulphuric acid, sp. gr. 1·060. This battery remains in constant action and working order for eight days, at an outlay of only 2 francs. When the objects which are galvanically tinned are afterwards heated to the melting-point of tin, the goodness and durability of hot-tinned materials is thus obtained. Copper thus tinned (galvanically), and afterwards heated, is superficially converted into bell-metal, while the method of tinning galvanically has the great advantage over the old method, that it can be applied to objects to which the method of tinning in ordinary use is not applicable.

Automatic Steam-Boiler Feeding Apparatus with Constant Level.—M. Macabies.—In a few words, we call attention to an excellent piece of useful apparatus, not a toy or complicated mechanism requiring highly-skilled labour for superintendence. It is placed on the boiler, and, as soon as steam is up, begins its work, and acts uninterruptedly, pumping, or rather sucking, either cold or boiling water, even from great depths, and forcing it regularly into the boiler. There are no parts in the apparatus liable to get out of order; and, though its construction and mode of action could not be well understood without woodcuts, its main principle and action is that of the well-known Monte-Jus.

New Source of Quicksilver.—A layer of quicksilver ore has been recently discovered in the district of Sarawak, Borneo, which ore promises to be one of the richest in the world. A trial of a large quantity of this ore has been made, and proved to yield from 70 to 80 per cent of metal; this ore is, therefore, very nearly pure sulphide of mercury, and is of very rare occurrence, since the average of mercury ores yet known do not contain more than from 2 to 20 per cent of metal. Borneo is rich in minerals of all sorts, and the ores found there are of exceedingly good quality.

Researches on Tobacco.—M. Schlœsing.—Most of our readers will be aware that the sale of tobacco is a monopoly of the French Government; but it is not so generally known that, at the very extensive central manufactory at Paris, there is established a very well-arranged chemical laboratory, where researches are being continually conducted with tobacco, in its various stages of preparation, as well as in its green, or, rather, raw-dried state. There are very few substances produced, either by the vital functions of plants or animals, which contain so large a variety of different chemical compounds as tobacco does. The inorganic substances it contains are:—Potassa, lime, magnesia, oxides of iron and manganese, ammonia, nitric, sulphuric, hydrochloric, and phosphoric acids, and silica. The organic substances are:—Nicotine, $C_{10}H_7N$; malic, citric, acetic, oxalic, pectinic, and ulmic acids; nicotianine; a green and yellow resin; wax and fat; albumenoid substances; and cellulose. Nicotianine, also known as tobacco camphor, is a fatty substance, exhibiting the pleasant aromatic odour of tobacco-smoke, and having an aromatic bitter taste. Nicotianine is probably identical with coumarine. Nicotine is an organic base; it is, in the pure state, a colourless, oily liquid, of very acrid taste; soluble in water, alcohol, ether, and oil; and a most dangerous poison. According to the author, the quantity of this substance contained in 100 parts, by weight, of dry unmanufactured tobacco-leaves, ripped from the stems, varies considerably, even for tobacco cultivated in France, from 7·96 to 3·24 per cent; for American tobacco, the quantity varies from 6·87 to 2·29 per cent; while the so-called Habana (properly Cuba) tobacco contains only 2·0 per cent of this alkaloid. Snuff, which contains on an average 33 per cent of water, contains 1·36 per cent of nicotine. The quantity of ash contained in tobacco in dry state varies from 19 to 27 per cent. 100 parts of the ash contain:—Potassa, 29·96; soda, 2·76; lime, 39·53; magnesia, 9·61; chloride of sodium, 9·65; sulphuric acid, 2·78; silica, 4·51; phosphate of peroxide of iron, 4·20. The more or less easy combustibility of tobacco does not depend upon the quantity of nitre it contains, since experiments made by the author have proved that the Kentucky tobacco, which contains a large quantity of saltpetre, burns badly, while Java, Maryland, and Hungarian tobacco, which contain hardly any saltpetre at all, burn very well. The author found that tobacco which burns badly, or not at all (at least, not so as to be suitable for the use of smokers), burns very well after having been steeped for some time in an aqueous solution of an organic potassa salt (oxalate, malate, citrate, or tartrate answer the purpose), and next dried. A well-burning tobacco becomes badly-burning, or even non-combustible, by being steeped in aqueous solutions of sulphate of lime, chloride of calcium, magnesia, or ammonia. The rationale thereof lies in the fact that the organic salts of potassa just alluded to yield, on combustion, a very bulky, porous, and light coal, which burns off readily on access of air. This paper contains some very important facts relating to the preparation of tobacco and snuff, obtained on a very large scale, working with some hundreds of thousands of tons annually.

Polytechnisches Journal von Dingler, second number for September 1869.

This number contains the following original papers relating to chemistry:—

Construction of Sulphate Furnaces (Sulfatöfen).—M. Lunge.—This paper is an excellent contribution to the technology of the manufacture of soda by M. Leblanc's process; but the paper is not well suited for abstraction, since there are added to it several engravings absolutely required for the proper understanding of the subject.

Manufacture of Sulphate of Alumina.—M. Pemberton.—Hydrate of alumina is mixed with sulphuric acid and water in the requisite proportions for the formation of neutral sulphate of alumina, $Al_2O_3.3SO_3+18HO$; the best proportions are 150 kilos. of moist hydrated alumina, containing 38 per cent of that hydrate, and 200 kilos. of sulphuric acid at 58° Beaumé (sp. gr., 1·678). These quantities yield from 325 to 340 kilos. of neutral sulphate of alumina, which crystallises readily. It should be borne in mind that no larger quantities than those just named should be operated with at one and the same time, because the chemical action which sets in is very violent, and if the heat thereby evolved becomes too great, the operation is spoiled.

Preparation of Indium in Pure State.—MM. Röszler and Wolf.—The authors make use of the Freiberg zinc for the purpose of obtaining indium. The zinc is dissolved in hydrochloric acid, and next boiled with excess of metallic zinc, whereby a spongy metallic precipitate is obtained of the following composition:—Lead, 1·36; tin, 0·02; cadmium, 0·13; copper, 0·004; indium, 0·075; together, 1·529 per cent of the metallic zinc employed. This mass is first treated with sulphuric acid to remove the lead. The whitish-coloured mass is next treated with boiling water; this solution is again treated with zinc, whereby a spongy metallic mass is obtained, which is acted upon by strong nitric acid, the excess of which is evaporated, and the oxides of tin and any remaining sulphate of lead are eliminated. The residue is taken up with water, to which ammonia is added, whereby the oxide of indium is precipitated; and, after drying, this oxide is reduced to the metallic state by means of cyanide of potassium.

Artificial Preparation of Anthracen.—Dr. Greiff.—The author prefers the preparation of anthracen from asphalte or pitch, instead of coal-tar, since the purification of the product is more readily effected when it is obtained from solid substances, by sublimation, in a manner somewhat similar to the manufacture of carbonate of ammonia. Too much and too long heating should be avoided. The quantities of anthracen yielded by tar, as well as by asphalte, vary greatly, and the cause thereof is not at present well ascertained.

Keeping Water in Tanks made of Zinc.—M. Ziurek.—The author calls attention to the fact that water kept in zinc vessels (reservoirs), or, also, collected from roofs covered with that metal, is invariably contaminated with that metal, and that the use of such water, either for domestic or industrial purposes, is highly injurious to health. The author recommends that, where zinc vessels are used for the purpose indicated, they should be painted over with asphalte varnish or any iron pigment.

Journal de Pharmacie et de Chimie, October, 1869.

This number contains the following original papers:—

Chlorides of Acetylen and Synthesis of the Chloride of Julin.—MM. Berthelot and Jungfleisch.—The authors have made perchloride of antimony act upon acetylen, which is very readily absorbed by this chloride with evolution of great heat, in consequence it becomes necessary to moderate the action, so as just to keep whereof the mixture in fluid state. On cooling, magnificent large crystalline lamellæ are deposited, which are a compound of acetylen and perchloride of antimony, $C_4H_2SbCl_5$. This compound is very unstable; it is immediately decomposed by water, and on the application of heat it is converted into perchloride of acetylen and protochloride of antimony, $C_4H_2.SbCl_5=C_4H_2Cl_2+SbCl_3$. Protochloride of acetylen, $C_4H_2Cl_2$, is a clear, colourless, very mobile liquid, exhibiting, in a high degree, the smell of chloroform; its taste is somewhat sweet, and its vapour causes headache; it boils at 55°; water, as well as moist air, decomposes it slowly; and if heated, along with water up to 180°, it is decomposed into hydrochloric acid and some volatile products. Heated to 360° in a sealed tube, it is entirely decomposed into a black carbonaceous mass and hydrochloric acid, without giving rise to any secondary products. Perchloride of acetylen, $C_4H_2Cl_4$, is a colourless fluid, exhibiting the smell and taste of chloroform; it boils at 147°; heated to 180°, along with water, it is slowly decomposed; brought into contact with chlorine gas, it is converted into sesquichloride of carbon. By cautiously treating this compound with an alcoholic solution of caustic potassa, hydrochloric acid is withdrawn, and protochloride of acetylen formed. Heated to 300°, for at least twenty-four hours, in a sealed tube, the chloride of julin is formed, which is obtained even better by allowing the heat to act up to 360° for 100 hours consecutively. The chloride of julin is identical with perchloride of benzine.

Boiling and Melting Points.—M. Fleury.—The determination of temperatures requires a correction for that portion of the column of mercury of the thermometer which is not itself immersed in the hot

medium. This correction is very liable to error, which may amount to even 10° or 15°. The author proposes the use of a metastatic thermometer.

Researches on the Bleaching of Tissues.—M. Kolb.—This paper contains the first instalment of a lengthy series of researches on this subject, but it is not well suited for abstraction.

Milk at Marseilles, and Milk in General.—M. Commaille.

Reagent for Copper and Iron.—M. Bellamy.—The alcoholic tincture of Campeachy wood, sometimes applied for the detection of bicarbonate of lime in potable waters, is, according to the author, a most valuable test for the detection of very minute quantities of iron or copper present in water. Both metals turn the colour of this tincture, when added to water containing minute quantities of the same, to a peculiar blue colour. According to the researches made on this subject, 1 grm. of iron, present in 20 cubic metres of water (rather more than 20 tons in weight), has the effect of being perfectly detectable by this tincture—that is, 1 part of metal in 20,000,000 parts of water; but after the water has been boiled, no reaction is observed. The metals are chiefly found in natural potable waters as carbonates.

Analysis of the Spring Water from Santa Catalina and Guadalupe (Canary Islands).—M. Méhu.—This spring, although only situated at 85 metres from the sea-board, does not exhibit any sign of being connected with the sea. The water of the spring is very clear, its taste saline, and the yield abundant; it reddens litmus paper; temperature, 26·66°. The dry residue from 1 kilo. of water, evaporated, and the residue dried at 180°, weighs 8·47 grms. The composition of the solid residue, expressed in grm. weight, is:—Chloride of sodium, 6·0921; chloride of potassium, 0·1080; chloride of calcium, 0·2833; bicarbonate of lime, 0·1482; bicarbonate of magnesia, 1·1654; sulphate of magnesia, 0·8766; silica, 0·1084; free carbonic acid, 1·0112. The weight of the anhydrous salts contained in 1 litre of this water amounts to 8·7828 grms. Guadalupe spring (*Gran Canaria*).—This spring is situated at a height of 210 metres above sea level, at a distance of 4 kilometres from the sea shore, and at 10 kilometres from the Santa Catalina spring. The temperature of the water of this spring is 29°, and it yields 514 litres of water per hour. The composition of the residue, after evaporation of 1 kilo. of the liquid, and drying at 180°, expressed in grm. weight, is:—Chloride of sodium, 0·11606; bicarbonate of soda, 0·79673; bicarbonate of potassa, 0·01978; bicarbonate of lime, 0·42251; bicarbonate of magnesia, 0·26473; sulphate of magnesia, 0·10700; silica, 0·11850; free carbonic acid, 1·05790. Weight of anhydrous salts to the kilo. of water, 1·845 grms.

Preparation of Nitrogen.—M. Levy.—When bichromate of ammonia is heated in a retort, that salt is converted into green sesquioxide of chromium, vapour of water, and pure nitrogen.

Revue Hebdomadaire de Chimie, October 28, 1869.

This number contains the following original papers and communications:—

Proper Mode of Sampling and Preserving the Samples of Raw Sugar for Quantitative Analysis.—M. Weinzierl.—The author calls attention to the discrepancies of the results of the analysis of raw sugars taken from the same large parcel, and submitted to investigation by different analytical chemists, in order to prove, by incontrovertible evidence, that, even when the samples are carefully taken (it is generally done by experienced brokers, who, being provided with proper tools, have thereby the means of taking from every box, cask, bag, kranjang, or basket, as the case may be, a fair sample representing the entire quantity contained in such parcel). The mode of keeping and preserving these samples may seriously interfere with the results of the analysis. For this purpose, the author has compared samples of raw sugar, kept in pasteboard boxes for 24, 48, 72, and 96 hours respectively—(1) kept in similar boxes inside lined with tin-foil; (2) kept in pasteboard boxes which were four times varnished with shellac varnish; (3) pasteboard boxes painted over with the paint ordinarily used for painting the sheet-iron sugar-loaf forms; (4) samples kept in tinned-iron boxes; and, lastly, samples kept in glass-stoppered bottles. The result of analysis of samples thus kept for 96 hours was as follows (the original sample, immediately on being taken, gave, in 100 parts—sugar, 91·70; water, 3·54; impurities, 4·76):—Sample-box 1, in 100 parts—Sugar, 92·90; water, 2·28; impurities, 4·86. Sample-box 2—Sugar, 91·90; water, 3·30; impurities, 4·80. Sample-box 3—Sugar, 92·40; water, 2·88; impurities, 4·72. Sample-box 4—Sugar, 91·90; water, 3·31; impurities, 4·79. Sample kept in tinned-iron box—Sugar, 91·80; water, 3·50; impurities, 4·70. Sugar kept in glass-stoppered bottle—Sugar, 91·70; water, 3·52; impurities, 4·78.

Reagent to Detect the Presence of Resin of Guaiacum among Resin of Jalappa.—M. Blacher.—When 50 centigrms. of pure and pulverised resin of guaiacum are mixed in a porcelain mortar with 20 centigrms. of black oxide of copper and about twenty drops of alcohol (not methylated spirits), nothing noteworthy is exhibited; but if to this mixture some fifteen drops of liquid ammonia are added, and trituration continued, there will be seen, within a minute, a beautiful apple-green colour. If this experiment is repeated, with the same quantities of material, but pure resin of Jalappa taken instead of the resin of guaiacum, the original brown colour of the latter remains predominant, and no greenish or bronzy colouration ensues. The quantities mentioned are not absolute, but the author thinks it best not to depart, in either more or less, from the same. There is formed a *guaiacinate ammoniaco-cuprique* (ammoniacal cupro-guaiacinate).

Nutritive Value of Divers Roots used as Cattle Food and for Sugar Manufacture.—M. Corenwinder.—The author has estimated the quantity of nitrogen contained in the following roots, and found that to amount, percentically:—In yellow beet-roots, 1·087 sugar beet-root, 1·044; rutabaga, 1·41; pulp of sugar beet-root, expressed by Champonnois process, 1·36. What rutabaga is is not explained. Although not an absolute criterion, the quantity of nitrogen contained in vegetables of this kind expresses fairly their average value as food, taking the other constituents into consideration.

Method for Staining Naturally White-Coloured Woods.—M. Mène.—When naturally-white-coloured woods are painted over with a concentrated aqueous solution of permanganate of potassa, which is best kept somewhat warm (tepid), it is possible thereby to give such woods the appearance of palissander or walnut wood. Different kinds of wood behave with this solution in different manner; the wood of pear and cherry trees is rapidly stained; white woods, as, for instance, the acacia (*Robinia pseudo-acacia*), resists a longer time; and resinous woods, like fir, are more difficultly acted on. The rationale is that the permanganate of potassa is decomposed by the woody fibre; brown peroxide of manganese is precipitated and fixed by the potassa, which is afterwards removed by washing with water. The wood, after having become dry, is varnished, and is, according to the author, not readily distinguished from naturally-dark-coloured woods.

NOTES AND QUERIES.

Halliday's Machines.—"A. W. N." will find, we think, the information he desires in Richardson's, Knapp's, and Watts's work on "Chemical Technology."

Bleaching Syrups.—Can some of your readers give me the following information:—What will bleach syrups (common sugar-house syrup) without expensive apparatus? Will animal charcoal effect the object to any degree?—Andrew van Bibber, Cincinnati, October 14, 1869.

Rendering and Bleaching Tallow.—(Reply to "A Tallow Melter.")—This correspondent is referred to Richardson's, Knapp's, and Watts's work on "Chemical Technology;" to Chevreul's work on Fats; and to Wagner's "Lehrbuch der Chemischen Technologie." There is a French publication on the subject in the useful series known as the "Encyclopédie Roret," published at Paris.

Tungstate of Soda, &c.—(Reply to "J. C.")—This article is not manufactured in such large quantities as to require special makers—some few manufacturing chemists make it, and also the tungstate of chromium; but we cannot name any who do so continually. If "J. C." wants these articles, he should either apply to those who sell chemicals, or to some manufacturing chemist, whose names can be found in directories.

Footpaths.—"Roadway" will find one part of Portland cement, mixed with seven or eight parts of gravel, or old hard durable rubbish, such as brick-bats, broken stones, or gravel, to make a cheap, neat, permanent, garden walk, impervious to wet, heat, or cold. I will give your correspondent any information he needs if he sends his address to me through you.—Nemo.

Footpaths.—(Reply to "Roadway.")—Your question is one which belongs to civil engineering, rather than chemistry; you do not state a very important item—viz., the natural soil you wish to make a footpath on. A very good and, comparatively, cheap footpath may be made by laying down, first, a layer of rather coarsely broken-up old bricks, next, some middling coarse gravel, and over that a layer of from 2 to 4 inches thickness of small sea-shells (bivalves). If care be taken to beat or roll the broken-up bricks and gravel well into a solid mass, the shell-covered surface may be advantageously rolled in with a heavy iron roller, and will be found to form, even on soft sub-soil, a durable and inexpensive roadway. On the continent, at least in Belgium and the Netherlands, many roadways, *chemins vicinaux et communaux*, are thus arranged, and stand moderate horse and carriage traffic admirably well. Care should be taken for the proper drainage of such roads.

Bichromate of Potash.—In answer to "Bichrome," in your last number, this article is made by Norris, Brothers, Sowerby Bridge, near Halifax; The Conacher Quay Chemical Company, 121, Newgate Street, London; by a Company at Drontheim, in Norway; and also at Baltimore, U.S. If your correspondent wants further information, and writes to me under cover to you, I will ascertain the other addresses.—Nemo.

Terra Alba.—"Selenite" thanks "Nemo" for information given and offered, and would ask further—Is any particular variety of gypsum preferred? what is the nature of Jullien's process? what precipitation is meant? how is drying effected? is the patent English? Also—If the purest gypsum answers, why the artificial product? what is the difference in cost of production of native and artificial? why is French better than English terra alba? any objection to mention uses of material?

TO CORRESPONDENTS.

Metallurgist.—(1) The latest and most complete treatise on Metallurgy is the English adaptation of Kerl, by Crookes and Röhrig; vol. i. 31s. 6d., and vol. ii., 36s., are published, and vol. iii. is in the press. (2) Mitchell's "Manual of Practical Assaying," edited by William Crookes; price 28s. These works can be obtained at our office. (3) A knowledge of your qualifications would be necessary to answer your other questions.

THE CHEMICAL NEWS.

VOL. XX. No. 520.

ON THE

ACTION OF CHLORIDE OF ZINC UPON CAMPHOR.

By M. ADOLPH ROMMIER.

ACCORDING to Gerhardt, when camphor is distilled over chloride of zinc, it changes into cymol and water, according to the following equation:—

$$C_{20}H_{16}O_2 = C_{20}H_{14} + 2HO.$$

MM. Lippmann and Longuinine,* Fittig, Koebrich, and Silke,† found great difficulty in preparing cymol from camphor, and observed during the reaction the formation of hydrocarbides homologous with benzol, which was also proved by ourselves upon repeating the experiment. Our experiments were made upon 2 kilos. of camphor, which when distilled four times over fused chloride of zinc, yielded about 700 kilos. of essence, which boiled at from 140° to 240°, and of which scarcely a tenth approached the boiling point of cymol. It was also ascertained that this essence, mixed with a solution of caustic potash, yields a product analogous to phenol. After precipitation by chlorhydric acid, 40 grammes were obtained, which, on distillation in a current of carbonic acid, yielded a small quantity of liquid, boiling below 200°, and the rest at a temperature somewhat higher. Here is the elementary analysis of this latter product:—

	Experiment.	Calculation.
Carbon	76·87	77·77 (C_{13})
Hydrogen	8·13	7·40 (H_8)
Oxygen	15·00	14·83 (O_2)
	100·00	100·00

figures which correspond to cresylic alcohol.

The first was too hydrated for analysis; it was merely heated with oxalic and sulphuric acids, and the formation of rosalic acid proved characteristic of phenic alcohol.

These phenols have a slight but decided smell of phenic alcohol, whilst cresylic alcohol, obtained from tar, has a very disagreeable odour, being less easily purified than that obtained from camphor. Finally, in the reaction of chloride of zinc upon camphor, the formation of the sundry hydrocarbides and phenols shows that, contrary to what was believed, decomposition with deflagration ensued rather than simple dehydration, since if the experiment was carried on at a low temperature, the camphor distilled without alteration, whilst if the temperature was raised to the fusing point of the chloride of zinc, a still greater quantity of camphor remained unaltered even after four distillations.

ON ARTIFICIALLY-COLOURED WINES.

By Dr. T. L. PHIPSON, F.C.S.

WHEN wine of any vintage is found to be wanting in colour, it is customary to mix it with a certain proportion of strongly-coloured wine grown in the South; for instance, with good Roussillon, &c. At Fismes and Poitiers, and probably in other parts of France, there exist, however, regular establishments where colouring-matter for wines is manufactured on a somewhat extensive scale.

* *Bulletin de la Société Chimique*, Nouvelle série tome, vii., p. 374, 1867.

† *Ibid.*, tome x., p. 78, 1869.

And in Greece the flowers of the purple Holyoaks (*Althæa rosea*, *Malva arborea*, *Rose tremiere*) are collected for the like purpose to a considerable extent.

The material manufactured at Fismes is obtained from elderberry, both from the fruit of *Sambucus niger* and *S. ebulus*. The process is very simple. 250 to 500 parts of this richly-coloured fruit, with 30 to 65 parts of alum, and 600 to 800 of water, are the proportions generally employed. It has been stated that beet-root juice, blackberries, Brazil-wood, logwood, &c., are occasionally used, but, I believe, by no means so frequently as the substances above named.

Many methods have been tried in order to detect the presence of artificial colouring-matters in wines, but, it appears, with a very small amount of success. Œnocyanine may be precipitated from the wine, and its properties, studied with care, will show at once the presence of an adulterating material; but the process is rather long and delicate. I have shown, in a note on the "Absorption Spectra Yielded by Certain Organic Substances,"* that the pure colouring-matter of the grape gives no absorption bands, but only a general absorption, increasing gradually towards the violet; whilst the colouring-matter of the purple Holyoak, dissolved in water containing a little alum, gives a distinct and wide absorption band in the neighbourhood of D. This allows its presence in wine to be detected without much difficulty; and the same method applies equally well to the colouring-matters of logwood and Brazil-wood.

I have not yet ascertained how the colouring-matter of elderberry fruit affects the spectrum, but it is not difficult to discover in wine, according to M. Fauré, by means of gelatine. The fact is that œnocyanine is easily precipitated along with the tannin when gelatine is added to red wine, whilst other colouring-matters (and, among them, that of the elderberry) are left in solution. If there happen to be not enough tannin naturally present in the liquid to precipitate all the œnocyanine, a little more must be added.

Alum will be often found in wine which is artificially coloured; it vivifies the tint, and is supposed to preserve the wine. Its presence is not only highly injurious to the health, but will effectually prevent the ripening of wine and the development of the bouquet.

The test to which I have called attention may be made as follows:—Take a specimen of the wine to be examined, and, if its colour is too powerful when examined in a thin tube by means of the prism, it must be diluted with distilled water until a proper degree of transparency is obtained. A minute quantity of alum is then added, and the specimen examined in the spectroscope. If an absorption band of any kind shows itself, the wine may be suspected.

Analytical Laboratory, Putney, S.W., Nov. 1st, 1869.

ON THE

METHODS OF ANALYSIS AND THE COMPOSITION OF VARIOUS CHEMICAL MANUFACTURING PRODUCTS.

By M. GASTON TISSANDIER.

(Continued from p. 218.)

SALTS OF SODA.

COMMERCIAL salts, or carbonates of soda, are divided into hydrated salts and dry, or anhydrous salts. In most cases, the determination of the alkalimetric standard suffices to show the value of the product. The method of preparing the standard liquid sulphuric acid, which is very important, is as follows:—

* *Journal of the Chemical Society*, Sept., 1869, p. 324.

Alkalimetric Standard Liquid.—The method which I prefer, and which may be called *méthode des tatonnements*, is as follows:—

Take pure commercial sulphuric acid, and weigh rather more than 100 grms. to the litre, in order to compensate for the proportion of water which is always contained in it. Let us suppose that 10 litres of standard liquid are required; a large bottle must first be gauged, by weighing into it 10 litres of distilled water, and marking the line made by the upper surface of the liquid with a stroke of a file. This done, half the water is poured away, and, to what remains, 1·200 grms. of pure commercial sulphuric acid are gradually added; the 10 litres are then filled up with distilled water. The liquid must now be stirred; and if the acid is of a good quality, the real composition of the normal liquid will be nearly arrived at, for the 200 grms. previously weighed will approximatively compensate the excess of water contained in the acid. The liquid will contain about 100 grms. of SO_3,HO per litre; but a mere approximation will not suffice, as extreme exactitude is indispensable. This first liquid must, therefore, be tested, in order to see whether it is too concentrated or too weak; that is, whether water or sulphuric acid must be added.

The test is easily effected with dry and pure carbonate of soda, which should estimate 92·40°, if the liquid is quite correct. It is a good plan to prepare the carbonate of soda one's self, in the following manner:—Fill, with bicarbonate of soda, a funnel, the lower part of which is provided with a plug of amianthus; wash the salt with water, so as to purify it and to eliminate the alkaline sulphates and chlorides with which it is mixed. When the rinsing-water no longer contains either chlorine or sulphuric acid, the bicarbonate of soda is pure; it must then be crystallised and calcined, when carbonate of soda is produced. To obtain still more exactitude, this is again dissolved, crystallised, and calcined, and it will then be perfectly pure and dry, and should estimate 92·40°.

In testing the alkalimetric liquid, it is a good plan to heat the carbonate of soda before weighing, and even to calcine it slightly, in order to separate the water which it may have absorbed; 5 grms. are then weighed, and their standard taken. If this proves to be too high—say, for instance, 94°—the liquid is too weak, and a small quantity of sulphuric acid must be added. By thus feeling the way, as it were, adding now more acid and now more water, a liquid is easily obtained which will give, in combination with the dry, pure carbonate of soda, a normal standard of 92·40°.

In order to avoid error, it is indispensable that the alkalimetric burettes employed should be scrupulously exact; they should, therefore, be tried—the best way of doing this is by means of the balance. A small precipitating vessel should be tared upon the pan of a sensitive balance, and distilled water poured into it from a burette. If the burette is correct, the volume of water contained between ten divisions, or 5 c.c., must be 5 grms.

Still greater exactitude may be obtained by testing the standard acid with protoxide of lead as follows:—Weigh 20 grs. of pure litharge, and heat them, in a small capsule, on a Gay-Lussac stove at 110°, until their weight no longer decreases; pour in 10 c.c. of the alkalimetric standard liquid, which, if correct, should contain 1 decigrm. of sulphuric acid, SO_3,HO; evaporate the whole to dryness on the stove, and weigh again. The increase of weight should be exactly 0·0816 grs., corresponding to the quantity of SO_3 contained in 0·1 gr. of SO_3,HO.

Too many precautions cannot be used in order to obtain a well-prepared normal liquid, which is of the utmost importance in working analyses. Some chemists are in the habit of estimating the sulphuric acid contained in 5 c.c. of the liquid; for this purpose, chloride of barium is used; and a well-performed experiment on a correct liquid should yield 0·2378 of sulphate of baryta, corresponding to 0·1 gr. of SO_3,HO.

Analysis of Dry Soda-Salts.—We will say nothing concerning hydrated carbonates of soda, which often contain more than 60 per cent of water; it is only necessary to remark that the alkalimetric standard is very important, as it often exposes the fraud of dealers. The method which we are about to describe, for analysing dry salts of soda, may also be applied to hydrated salts.

Weigh 25 grms. of the salt to be tested, dissolve in water, and filter the insoluble substances upon a filter placed above a test-glass gauged to ½ a litre. The liquid ½ litre is divided in the following manner:—

Remove 100 c.c., corresponding to 5 grms., to ascertain the alkalimetrical standard. By stating the equation—

$$\text{Standard, or number of divisions on the burette} = \frac{49(SO_3HO)}{53(CO_2NaO)}$$

the carbonate of soda per cent is obtained. Deduct 50 c.c., to estimate the chlorine, which is transformed into chloride of sodium, and 100 c.c., to estimate the sulphuric acid, which is changed into sulphate of soda. The estimation of the moisture is effected separately in a platinum crucible. Those who wish for a description of the process are referred to former chapters.

Composition of Salts of Soda.

Substances estimated.	I.	II.	III.	IV.	V.
Moisture	2·22	3·11	1·15	1·00	0·40
Insoluble matter ..	0·12	0·22	0·08	—	0·06
Chloride of sodium..	12·48	6·41	3·28	2·11	0·99
Sulphate of soda ..	8·51	3·25	2·15	1·50	0·35
Carbonate of soda ..	76·67	87·01	92·34	95·39	98·20
Total.. ..	100·00	100·00	100·00	100·00	100·00

Salts of soda derived from the refining of beet-root salts always contain a small quantity of potash, which may be easily estimated by means of bichloride of platinum.

Estimation of Caustic Soda.—Salts of soda sometimes contain caustic soda, the proportion of which may be determined in the following way:—

Pulverise part of the specimen finely, throw it into a stoppered flask, into which have been previously poured 100 c.c. of alcohol at a temperature of 40°, and stir vigorously for ten minutes. The alcohol does not dissolve the soda, while at the same time it absorbs the whole of the caustic soda. Filter under a bell-glass, in order to avoid evaporation of the alcohol; collect 50 c.c. of the liquid, which will correspond to 5 grms. of salt, saturate it with the alkalimetric liquid in the cold, adding water and a few drops of sensitive litmus, and the *standard of causticity* will be obtained. This standard allows the calculation of the corresponding quantity of caustic soda, NaO,HO, deducted from the total standard; the difference given will be the standard corresponding to the carbonate of soda.

Composition of Salts of Soda containing Caustic Soda.

Substances estimated.	I.	II.	III.	IV.
Moisture	2·10	1·50	2·48	1·38
Insoluble matter ..	0·12	0·11	0·21	0·09
Chloride of sodium	4·32	2·43	3·50	4·11
Sulphate of soda ..	8·88	1·62	2·15	2·50
Carbonate of soda	82·47	88·09	84·54	81·67
Caustic soda.. ..	2·11	6·25	7·12	10·25
	100·00	100·00	100·00	100·00

Detection of Iron and Sulphides.—Salts of soda destined for the manufacture of glass should be free from iron (which colours the glass), and from alkaline sulphides. Iron may be detected by means of sulphydrate of ammonia, or, which is better, sulphocyanide of potassium, the most sensitive reagent of that metal. If the solution of the salt under examination should contain traces of iron, it will assume a red hue under the influence of some drops of this reagent poured into an acidified liquid. To detect sulphides, boil the salt of soda to be tested in a

flask containing sulphuric acid diluted with water. The liberated sulphydric acid may be known by its smell, or by the influence which it exerts upon paper previously soaked in acetate of lead.

NITRATES OF SODA.

The analysis of nitrates of soda requires great care; for the amount of nitrate contained in them is determined by difference.

Estimation of Moisture.—Heat 5 grms. of the specimen on the stove at 120° until they no longer lose weight. The method of the closed tube, previously described, may also be employed.

Estimation of Chlorine.—Nitrates of soda do not usually contain more than from 1 to 1·60 per cent of chloride of sodium; therefore the estimation must be made upon 10 grms. with the silver liquid.

Estimation of Insoluble Substances.—Dissolve 25 grms. of nitrate of soda in water, and separate the insoluble matters by filtration. They, however, occur in but small proportions.

Estimation of Sulphuric Acid.—This is estimated on 25 grms. of nitrate of soda. The filtered liquid is now used for this purpose, having previously served to determine the quantity of insoluble substances. The sulphuric acid is precipitated as sulphate of baryta, and filtered after standing twelve hours.

Subjoined is an example of the composition of some commercial nitrates of soda, and of the way in which it is usual to formularise the analytical results obtained.

Loss per cent.	I.	II.	III.	IV.
Moisture	0·98	1·11	1·42	1·68
Insoluble matters	0·07	0·12	0·16	0·15
Chloride of sodium ..	0·99	1·10	1·41	1·60
Sulphate of soda	0·18	0·20	0·22	0·25
Total loss	2·22	2·53	3·21	3·68
Nitrate of soda	97·78	97·47	96·79	96·32
Total..	100·00	100·00	100·00	100·00

The quantity of water contained in nitrates of soda rarely exceeds from 2 to 2·50 per cent. The proportion of nitrate of soda varies between 95 and 99 per cent.

(To be continued).

ON MICROSCOPICAL MANIPULATION.*

By W. T. SUFFOLK, F.R.M.S.

(Continued from p. 221.)

THE durability of objects, however mounted, is much influenced by the manner of storing them. Racked boxes and drawers are the worst possible receptacles as from the vertical position of the slides they are liable to serious injury, those in fluid being likely to become leaky, and the balsam specimens sliding down, frequently, cover and all. Arrangements should be made for keeping the objects flat, which is now always done in well constructed cabinets; it is also a great advantage to be able to see every slide, which is impossible in a racked box, and often causes much loss of time in searching for an object. For the convenience of those for whom the usual cabinets are too costly, Mr. Piper has invented some very ingenious trays, in which slides are placed horizontally; besides the merit of cheapness, they have the advantage of being extremely convenient. Five or six of these trays, with a mill-board at the top and bottom, may be fastened together with a couple of India-rubber rings, and any vacant shelf room utilised for the storage of objects; a similar bundle of two or three trays is very convenient for carrying a small selection of objects in the pocket. Dr. Carpenter has used these trays placed in wooden cases made to resemble books, a very convenient way when bookshelves are vacant to receive them.

The chief difficulty of fluid mounting will be found not to consist so much in the mechanical process of closing the object perfectly in its cell, as in the selection of a fluid suitable for its preservation.

A fluid which may be considered as a perfect medium—that is, one capable of preserving substances for an unlimited period without change, is at present unknown, and it is more than doubtful whether the discovery of such a fluid would be altogether an advantage, as use is frequently made of what some may consider the defects of preservative fluids, the alterations they induce in tissues submitted to their action often revealing facts of great importance. Some media are valuable, because they soak into tissues and render them transparent; this is the case to such an extent with glycerine, that Dr. Beale very appropriately calls it "The Canada balsam of moist tissues." Others are used for quite the opposite purpose, because they induce opacity, and very frequently do so partially, bringing out details somewhat in the same manner as is done by the colouring of a map, and which, without such aid, would be very imperfectly distinguished. Others are slightly corrosive, and clear away parts wished to be got rid of for the sake of bringing others more prominently into view.

In mentioning some of the very numerous media which have been used for mounting, the results can only be stated generally, and no fixed set of rules can be given, as the whole subject is at present in too imperfect a state. Much good might be done by observers mounting a series of the same object in different media, carefully labelling each slide with the date of mounting and the nature of the medium employed, and from time to time noticing and recording the result.

One of the great difficulties affecting the mounting of objects in fluid, arises from endosomotic action. When two fluids of different densities are separated by a permeable membrane, they will pass through and mix at very unequal rates. Supposing some dense fluid, like glycerine, enclosed in a bladder and immersed in water, the water would flow into the bladder faster than the glycerine made its way out, the result would be the expansion of the bladder. This is called endosmosis: the reverse action is known as exosmosis. With a view to observing practically the result of these actions, the student is recommended to obtain a specimen of some fresh-water conferva, such as are abundant in nearly every pond or aquarium. A portion of this conferva should be placed on a slide in a drop of water, covered with a thin glass, and examined with a power of fifty or sixty diameters. When the appearance of the plant is well impressed on the mind, remove the slide from the microscope, take off the cover glass from the object, and with a piece of blotting-paper drain off (not blot up) as much of the water as possible. Now cover the conferva with some strong glycerine, replace the cover quickly, and examine without loss of time under the microscope, and notice the change that has taken place. The fluid contents of the

* The substance of a course of lectures delivered to the members of the Quekett Microscopical Club, January—April, 1869.

conferva cells have suddenly emptied themselves into the surrounding glycerine, leaving the whole plant in a shrivelled and contracted state; in many cases the cells will be found to be ruptured, but those which have escaped injury will after a time expand and resume their natural appearance. In observing, advantage is sometimes taken of induced endosmosis, the tissues ruptured by this means often revealing points of structural detail difficult or impossible of demonstration by dissection. Endosomotic action may be prevented by introducing objects which contain light fluids very gradually into denser ones; for instance, an object should be passed from water into weak glycerine and then after a time into stronger, till at last it might be placed in glycerine of full strength without any contraction taking place. The same phenomenon takes place if marine plants are immersed in fresh water. This may be familiar to some who have attempted to wash delicate sea weeds, such as *Griffithsia setacea* in fresh water, the result being that the cells burst and stain the mounting paper; this may be prevented by washing in sea water, or water having gum or sugar dissolved in it, so that its specific gravity approaches that of sea water. An ingenious application of the principle of gradually increasing the specific gravity of the mounting fluid with a view to the prevention of endosmosis, will be found in the method known as Hantzsch's. The fluid consists of three parts alcohol, two of distilled water, and one of glycerine (Price's), all by measure. This medium is principally imployed in mounting *Algæ*. The specimen is placed in the cell with this fluid and the cover put on, but not cemented, so as to allow evaporation to take place; the waste is supplied from time to time, until at last the cell contains nearly pure glycerine; it is then to be cemented as before described. The fluid is of very nearly the same specific gravity as water, so little or no endosomotic action takes place on the immersion of the specimen; and as the evaporation process increases the strength of the solution very gradually, the most delicate tissues can be eventually mounted in strong glycerine; doubtless this principle would answer equally well with a solution of chloride of calcium, a very valuable medium for certain preparations. Much valuable information respecting the collection and preparation of *Algæ*, will be found in "The Collector's Handy Book of Algæ," by Rev. W.W. Spicer, from which the above process is taken.

Taking the preservative fluids in groups, the simplest consist of water, either alone or in combination with some antiseptic substances.

Distilled water alone is capable of preserving such objects as the *Desmidiæ* and other *Algæ* in tolerable perfection as to form, although with more or less loss of colour and alteration of the disposition of the endochrome or cell contents. Confervæ are very apt to grow in slides in which distilled water is used; this is best prevented by saturating the water with camphor or creosote.

Camphor water is made by placing a lump of camphor in a bottle of distilled water, and allowing it to remain a few days; the water will then be found to smell very strongly, although the quantity dissolved is exceedingly small. Such portion as may be required for use is to be filtered and kept in a small bottle; the store bottle is to be filled up from time to time with distilled water. This fluid may be used with advantage in making and diluting all the preservative fluids mentioned in these papers instead of pure distilled water, unless an indication to the contrary is given in the formula. It is capable of preserving animal tissues as well as vegetable, but with the fault of most watery liquids, that it is apt in time to induce a granulous texture in objects of this kind mounted in it.

Creosote water is made in a nearly similar manner; a few drops of creosote are poured on a quantity of precipitated chalk, and the whole shaken up in a bottle of distilled water. When the chalk has settled, the clear liquid may be poured off and filtered as required for use; the preservative properties of this and also of a very diluted solution of carbolic acid closely resemble those of camphor water. For another use of carbolic acid see paper by Dr. Bastian, before quoted (Chemical News, vol. xx., p. 96.)

Alcohol diluted with water, in various proportions, is much used for the preservation of large anatomical specimens; portions of injected tissue to be viewed as opaque objects keep very well in it, also vegetable structures where loss of colour is not objectionable. The striated structure of muscular fibre is well shown when this medium is employed; a piece of cooked meat will do to experiment upon. The fibres should be well separated with the needles before the cell is closed. Many other preparations are used for the preservation of objects.

Thwaites's Fluid.—Water, 16 ozs.; alcohol, 1 oz.; creosote and chalk, as in creosote water. Pour the creosote on the chalk as before, add the alcohol, stir up the whole, and add the water very gradually; allow the mixture to stand a few days, and then filter. Dr. Beale found that this solution was liable to become thick after a time, and gives the following substitute in his "How to Work with the Microscope:"—"Creosote, 3 drachms; wood naphtha, 6 ounces; distilled water, 64 ounces; chalk, as much as may be necessary. Mix first the naphtha and creosote; then add as much prepared chalk as may be sufficient to form a smooth, thick paste; afterwards add very gradually a small quantity of the water, which must be well mixed with the other ingredients in a mortar. Add two or three small lumps of camphor, and allow the mixture to stand in a lightly-covered vessel for a fortnight or three weeks, with occasional stirring. The almost clear supernatant fluid may then be poured off and filtered if necessary; it should be kept in well corked or stoppered bottles." Dr. Beale states that he has had large preparations preserved in this fluid for more than twelve years, and that it is still bright and colourless.

Fluids are filtered by being strained through a conical bag made of a circular piece of porous paper manufactured for the purpose, folded in the usual manner, and supported in a glass or porcelain funnel of suitable dimensions. If the proper filtering paper is not at hand, white blotting paper will answer the purpose.

Chloride of Calcium (a saturated solution in camphor water.)—For making this solution, the pure fused salt should be used, and not the common kind used for drying; it should be carefully filtered before use; it can be diluted to any extent with camphor water. The saturated solution is an extremely valuable preservative fluid; it soaks into objects, rendering them transparent, but rather less so than strong glycerine; it has the advantage, also, of not injuring calcareous tissues. Insects, viz., fleas and lice, mounted whole in this medium, with little or no compression, show the tracheal system and many of

the internal organs remarkably well when properly illuminated, and are still in perfect condition; date of mounting, 1866. Flax, hemp, and other similar fibres display their structure far better in this than in any other medium, the secondary deposits being very clearly brought out.

Diluted Solution.—One part of saturated solution to ten of camphor water, answers well for the preservation of the fresh-water *Algæ*; the green colour is better preserved by it than it is in any other fluid.

Chloride of Sodium (common table salt).—A saturated solution seems to preserve *Entomostraca* very well indeed; it induces a slight degree of opacity, which is sometimes an advantage. Specimens of *Daphnia pulex* (water fleas) mounted in it in September, 1866, show much of the internal structure; the eyes and bundle of optic nerves are in very perfect condition. This solution is of value from its being readily procured anywhere, and a supply of specimens which would otherwise be lost may be preserved in it. Sea water impregnated with camphor or creosote will reserve various delicate marine animals and plants extremely well and without injury from endosmosis; by taking proper precautions they may be gradually transferred, if necessary, to strong glycerine.

Solution of arsenious acid in water has been used both alone and in combination with glycerine for the preservation of objects; the latter mixture has answered very well in re-mounting a series of injected preparations, which are now, after a period of about six years, in perfect condition. The quantity of arsenic capable of being dissolved in water is extremely small; solutions of arsenic, unless saturated with camphor, are especially liable to confervoid growths, a rather unexpected phenomenon in so poisonous a fluid.

(To be continued.)

THE CHEMISTRY OF THE BLAST FURNACE.*

By I. LOWTHIAN BELL.

My attention has just been directed to a translation of an article in your journal by Mr. C. Schinz, of Strasburg, entitled "The Chemistry of the Blast Furnace according to Mr. I. L. Bell's Experiments." In a subject, the investigation of which is attended with so many practical difficulties as this, we can scarcely hope to discover the exact truth at once, and I think I can now amend—indeed, I may say, I have in a recent paper amended—to a small extent, the views communicated to my colleagues in the Chemical Society of London, in the paper of which the article in question is a criticism. I shall at all times be glad to have my opinions freely canvassed; but in the present instance Mr. Schinz has overlooked those minor parts of the inquiry in which I have probably erred, and attacks me in language a little more forcible than is perhaps strictly necessary upon matters where I hope to show the fallacy is all on his side.

In my discourse to the Chemical Society, I expressed a dissent from the view which maps out a furnace into zones of strongly defined dimensions, and gave my reasons, one of which was the irregularity of the size of the pieces introduced into its interior. Mr. Schinz says this mode of charging a blast furnace is a mistake often committed in England. I said nothing to the contrary; I am dealing with the effect, not with the cause, and leave the practical smelter to discover whether the saving in fuel by a different mode of procedure will pay for the expense incurred in its adoption. I have stated elsewhere† that where such an expensive fuel as charcoal is employed, more care is taken in this item than with us, but observation in almost every iron-producing country in Europe enables me to challenge Mr. Schinz to name one instance where the approach to uniformity of dimensions in the materials is usually such as he would have us suppose.

The measurement of temperatures of the escaping gases of blast furnaces is assumed as being founded "upon a delusion;" because, as this gentleman observes, pieces of metals such as I employed laid on the bottom of the gas pipe, will, from their superior conducting power, not be melted by reason of their contact with the cool pipe, while ore exposed to the current of hot gases, will, from its less conducting power, acquire a temperature superior to that indicated by the non-fusion of the test metals. Now there is not one word in my paper to justify any such inference as to the mode followed in estimating the temperature of the gases; for it happens the specimens of ore operated upon in the experiments quoted were suspended by a thin rod on a tray 2 or 3 feet from the side of the gas pipe and the metals intended to denote the temperatures were placed on the same tray (6 inches square), so that all must necessarily have been equally heated. Besides, Mr. Schinz might have given me credit for more care in obtaining my data, seeing I mention the use of three different kinds of pyrometer, not one of which could, without great difficulty, have been applied in the blundering way he suggests.

But, continues this chemist, if my observations as to temperature are true, "my conclusion" is still only delusively correct, "because reduction is accelerated by proportionate quantity of gas, by the amount of carbonic oxide such gas contains, and by its temperature." Before Mr. Schinz undertook to correct me, I had published an account of experiments* undertaken to show how these three conditions affect the rapidity and extent of reduction, but neither of these phenomena is in question in the present discussion. Former experimenters had given the results of their observations as to the temperature at which reduction *begins* in a blast furnace, and I gave the grounds for respectfully dissenting from opinions entertained by such eminent men as Tunner, Ebelmen, and Scheerer.

Mr. Schinz then proceeds to pass an opinion upon Tunner's analysis of the gases of the Wrbna furnace, which he says is "decidedly wrong," and then observes that the composition given of the gas of one of the Clarence furnaces is "just as false."

I may fairly leave the reputation of my friend, Professor Tunner, as a correct observer, to stand upon its own merits, and reserve my observations for pointing out to Mr. Schinz what is really involved in his somewhat gratuitous observation respecting the analysis of the Clarence gases. I quote the results obtained as they are given in my paper:—

Volumes in 100 Volumes.	CO_2		CO		N by Difference.	
Hour of taking Sample, p.m.	1st Trial.	2nd Trial.	1st Trial.	2nd Trial.	1st Trial.	2nd Trial.
1.0	6·25	—	26·30	—	67·45	—
1.55	6·24	6·70	34·70	—	59·06	—
2.15	6·94	6·73	34·40	35·40	58·66	57·87
3.0	5·30	5·75	35·80	35·64	58·90	58·61
3.15	4·75	5·12	31·00	30·25	64·25	64·63
3.55	5·91	—	31·12	—	62·97	—
4.20	5·82	6·00	29·72	28·90	64·46	65·10
Average being	5·88	—	31·86	—	62·26	—

Now, if the above figures had been obtained by an incompetent operator, one would have expected to have found discordant results upon the repetition of the analyses, and there being no evidence whatever of this, the

* Communicated by the Author simultaneously to the CHEMICAL NEWS and *Engineering*.

† Paper on our foreign competitors in the iron trade.

* Paper read at Middlesbrough meeting of Iron and Steel Institute, September, 1869.

word "false," used by Mr. Schinz, has, to my mind, a somewhat unpleasant sound.

To its application, however, I must submit, if this gentleman is correct in his assertion that furnace gas, having a composition like that given, is "almost impossible;" for he proceeds to show how, taking the nitrogen as the basis of his calculation, the quantity of oxygen, and hence of carbon, are incompatible with the ratio in which the first two elements exist in the atmosphere, having, of course, regard to the oxygen in the ore. In the estimate which has to prove how false my data are, Mr. Schinz assumes that the sole sources of oxygen are the blast and the ore, for he never gives a thought to the *limestone*. Now this is the less excusable, seeing that in the very next page in my paper, the theoretical composition of furnace gases is compared with that furnished by analysis, and the sources of each of the constituent parts are given, among which the limestone is distinctly mentioned. I shall not trouble you with all Mr. Schinz's figures, but content myself with giving a statement, by which it will be seen how nearly the analysis agrees with what the furnace was using at the time the gases were collected for the examination, assumed by this gentleman to be so incorrect.

The consumption for each ton of iron at the time was:—

	cwts.
Coke	29·50
Limestone, calcined, and containing about 22 per cent of carbonic acid	15·50
Ironstone	49·50
The coke contained of carbon	27·14
" " ash, moisture, &c.	2·36
	29·50

The carbon which would be volatilised was:—

That contained in the coke	27·14
" " limestone partially calcined	0·93
	28·07
Less that to combine with the iron..	0·74
	27·33

The gases of which the volumetric analysis is objected to by Mr. Schinz had the following composition:—

By volume.	By weight.		
CO_2 5·88	8·94	Carbon	15·65
CO 31·86	30·82	Oxygen	24·11
N 62·26	60·24	Nitrogen	60·24
100·00	100·00		100·00

From these proportions, the gases for each ton of iron will consist, by weight, of—

	Cwts.		Carbon.	Oxygen.
Nitrogen	105·20		—	—
Carbonic oxide..	53·83	=	23·07	30·76
Carbonic acid ..	15·61	=	4·26	11·35
	174·64		27·33	42·11

Thus, then, 42·11 cwts. of oxygen are associated with the 27·33 of carbon set out with as having been volatilised. For this we have oxygen accompanying the nitrogen found

	cwts.
in the gases, which would be—105·20 × $\frac{8}{21}$	31·42
The iron in 20 cwts. of pig is 19 cwts., which, as peroxide, is equal to oxygen..	8·14
Oxygen combined with 0·93 carbon in the carbonic acid of limestone	2·48
	42·04

instead of 42·11, which will probably be accepted as a nearer approximation to truth than the words "almost impossible" would seem to convey.

The actual numbers objected to by Mr. Schinz were CO_2 6, CO 32, N 62, which was merely the volumetric composition of a mixture made for the purpose of comparing its effect in deoxidising iron ore with that of a second mixture, made to resemble the gases of the Wrbna furnace. These numbers, it will be perceived, closely resemble the analysis just examined.

This omission of limestone, as contributing to the constituents of the furnace gases, is repeated by Mr. Schinz when he examines my comparison of the gases produced by the use of hot and cold air in Wales, neither of which, it is expressly stated, were analysed, but assumed as resembling those of the Clarence Works for the sole purpose of estimating the quantity of heat carried off by their means.

In these instances, the gases were considered as consisting, by weight, of CO_2 9, CO 32, N 59; numbers which differ but slightly from those deduced from the analysis of the Clarence gases, as formerly stated.

I find I have made two errors in the calculation based on this assumption. The weight of gases from the cold blast

	CO_2.	CO.	N.	HO.	Total.
furnace should be ..	18·20	64·70	119·40	3·93	206·23
instead of, as formerly	18·19	64·73	124·60	3·93	211·45
and from the hot blast it should be	13·50	48·10	88·60	3·06	153·26
instead of, as before	12·94	46·22	92·73	3·06	154·95

The difference, however, between these two sets of figures is so small as not materially to affect the conclusions drawn from them; but Mr. Schinz arrives at a very contrary opinion by changing the weight of nitrogen, given above in the case of the cold blast furnace, from 124·6 to 142·6, and, not satisfied with this mistake, commits another in the arithmetic used in working out the result from the hot blast furnace, by which he makes the ratio of the volumes of carbon vapour and oxygen per 100 volumes of nitrogen to be 35·82 of carbon and 41·22 of oxygen instead of 29·4 and 33·8 respectively.

In alluding to my remarks on the hot blast, Mr. Schinz (*à propos* of nothing I said) mentions that, "with cold blast an increase of fuel will always yield a product richer in carbon graphite, whilst an increase of temperature by means of the hot blast will never secure the same success." All I can say is the experience of twenty-five years with blast furnaces and that gained by a constant study of a present annual make of 120,000 tons of iron has produced no such impression on my mind. Neither am I disposed to accept as a "solution of the problem relating to the wonderful effect of the hot blast," Mr. Schinz's explanation, who considers solid carbon and not carbonic oxide as the reducing agent.

If my experiments are "worthless," the calculations of Mr. Schinz are not of a very accurate order, for he founds an estimate of heat units supplied to a furnace on the assumption that 113 kilos. of carbon require 3881 kilos. of air for conversion into carbonic oxide, whereas it ought to be 655 kilos. and equally so is his calculation which proves hot blast iron to require more fuel than that smelted with cold air.

I am censured, too, for not being able to distinguish between height and capacity in referring to the economy in fuel effected by a change in the dimensions of blast furnaces. My language may be defective in clearness, but it seemed to me that when I stated that the Lilleshall furnaces saved coal by an addition of 21 ft. to their height, none but a very fastidious critic could have imagined this alteration in form to have been made without their capacity having been increased to a corresponding extent.

There is little in Mr. Schinz's review of my work I am disposed to assent to, but I am unwilling to trespass further on your space, which I have been induced to do at some length in order that the Fellows of the Chemical Society, who honoured me by an invitation to give an address on applied chemistry, should not think I had complied with their request in the negligent manner this gentleman would have them believe.

Washington, Durham.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, November 4th, 1869.

Sir Benjamin C. Brodie, Bart., F.R.S., in the Chair.

The minutes of the previous meeting having been read and confirmed, the following certificates were read:—

For the first time—Sir Roderick Impey Murchison, Bart., Belgrave Square; John Wiggin, Pharmaceutical and Analytical Chemist, Ipswich; George Harrison, Analytical Chemist, 26, Havelock Square, Sheffield; Thomas Walton, M.R.C.S., and L.S.A., Lecturer on Chemistry at the Hull and East Riding School of Medicine, Kingston-upon-Hull; Edward Smith, Practical and Pharmaceutical Chemist, Strand, Torquay; G. Manley Hopwood, 22, Grosvenor Square, All Saints, Manchester; Thomas Gibb, A.R.S.M., Engineer; Matthew H. Cochrane, 108, Paul Terrace, Glasgow.

For the second time—E. S. Blackwell, Analytical and Consulting Chemist, 6, St. Sacrament Street, Montreal, Canada.

For the third time—Alfred Dudley Keightley, Gatcheck Gunpowder Mills, Old Hall, Milnthorpe, Westmoreland; W. Fletcher Barrett, Lecturer on Physical Science at the London International College; John Morrison, Analytical Chemist, County Wicklow, Ireland; Temple A. Orme, Teacher of Chemistry and Experimental Physics in University College School; W. G. Lewis, Fellow of Oriel College, Oxford.

The last-named gentlemen were ballotted for and duly elected. Mr. Gerstl was elected an Associate of the Society.

The Chairman said the first business before the Society was to consider a paper "*On the Atomic Theory*," which had already been read before the Society by Professor Williamson. This theory was not to be regarded as a fixed and definite system of ideas, but one that had undergone great variation and change. There was the atomic theory of Dalton; then that of Berzelius, and also, in a certain sense, that of Laurent and Gerhardt; and now they had come to a further form of this theory, in which new ideas had arisen in regard to the nature of atoms and their properties; and he (the Chairman) thought it would greatly facilitate the discussion if Dr. Williamson would explain what was the precise form of the atomic theory which he was prepared to maintain and defend, and how they might discriminate that from other forms of the theory which were neither reasonable, nor rational. First, there was the question whether there were atoms at all; then, being atoms, what those atoms were, and whether they were endowed with the properties assigned to them in regard to their replacing power, and to what was termed, their value.

Professor Williamson, on rising, said that he did not admit that, among chemists, there had been several atomic theories. If there had been, he had yet to learn of them. There had prevailed, he believed, from time immemorial, a belief that matter was built up of small particles; and he might also say that no contrary opinion had ever been embodied in any definite form. Dalton doubtless looked for evidences of what he believed to be true, and saw, in the simple multiple proportions which he specially alluded to, facts which were in accordance with that preconceived conviction; but his was the mere germ of an atomic theory, and the changes which have taken place in it since are consistent with the original notions. The very rapid changes had, in the main, been additions to the starting-point given by Dalton. The line of work so vigorously pursued of late years by many chemists, regarding the order in which atoms are arranged in their compounds, was mentioned by the speaker, His endeavour had been to put together more fully than had been done of late what is known of the chemical evidence; firstly, respecting the limits to the divisibility of matter, and, secondly, with regard to the properties of those finite particles which constitute the limits of divisibility, solely from the point of view habitually employed by chemists in their ordinary working. He had also endeavoured to separate those conclusions which appeared to him warranted by facts from everything else. Whether the smallest particles of matter had a spherical form or not, whether they were in their nature indivisible, whether they were in reality the ultimate atoms of matter, or like the planets of this system, he knew not, nor did such questions exist for him as a chemist. He therefore thought it wise to exclude them, important as they were, from the actually existing atomic theory. The work of Berzelius was perhaps the most significant transition from the original notion of Dalton. Silently these atoms had been accepted by chemists, and the whole course of investigation had been one grand confirmation of the assumption that compounds must have molecular weights corresponding to at least the smallest atomic proportion which would represent the actual numbers of analysis. The perfectly independent observations which had been made in reference to: the boiling points of homologous liquids, the phenomena of diffusion, the equality of volumes of masses containing an equal number of these molecules under similar conditions in the gaseous state, all concurred to corroborate the conclusions necessitated by the atomic theory. Thus, independent workmen hewed stones which, when hewn, were found to fit in exactly with the others, forming a perfectly homogeneous whole. Dr. Williamson concluded his remarks by referring to the atomic values, a term which, he thought, represented in a more precise way than some others what is called atomicity; and he also referred to the difference between direct and indirect combination, a fact which he conceived to be essentially atomic in its nature.

Dr. Frankland was not present when Professor Williamson delivered his lecture, and he had only cursorily looked over the printed memoir; but, so far as he could gather, the object of the author had been to establish the atomic theory as an absolute truth. There had been, he thought, so little, if any, opposition to the application of the atomic theory to the phenomena of chemistry, that a discussion could scarcely be raised upon any other feature of the question than that of its absoluteness. He considered it impossible to get at the truth, as to whether matter was composed of small and indivisible particles, or whether it was continuous—the question belonged to what metaphysicians termed "the unknowable;" but he acknowledged the importance of the fullest use of the theory as a kind of ladder to elevate the chemist from one position to another in his science. He was, however, averse to accepting the theory as an absolute truth. Any attempt to realise by its help the action of attractive or repulsive forces upon matter was excessively difficult, indeed to realise such an action through a perfectly void space was to him quite impossible. The same difficulty presented itself to Faraday, who was often obliged to throw on one side, as an obstacle to his progress, this atomic theory. He said that if matter be assumed to be thus composed of solid particles separated by a void space, then, in considering the phenomena of electricity in connection with that view of matter, this space existing between the atoms must be either a conductor, or a non-conductor of electricity. If a conductor, such a thing as an insulator was obviously an impossibility; if it was a non-conductor, such a thing as a conductor was equally inconceivable; so that, apart from chemistry, there were considerations which made it very undesirable for this theory to be represented as an absolute truth. The speaker then referred to the combination which, in certain cases, is effected between gases by the application of heat,

and said that, according to the atomic hypothesis, they must assume that the gases, when heated, have their particles driven further asunder; but how, then, could they more readily enter into combination when heated, as was the case with oxygen and hydrogen, and in many other similar instances? No such difficulty presented itself if the gases were regarded as continuous matter. He admired the theory as much as Professor Williamson, and he thought no one could blame him for not making a sufficient use of it; but he did not wish to be considered a blind believer in the theory, or as unwilling to renounce it if anything better presented itself to assist him in his work.

Dr. Odling, as a chemist, was not particularly interested in the question whether matter was infinitely divisible or not, but he did not think that Dr. Williamson's argument had established that conclusion. Dalton was always spoken of as the discoverer of the law, or doctrine, or theory of combination in definite and multiple proportions, to account for which his invention or adoption of the atomic theory was founded; and he conceived Dalton's great discovery to be better expressed as the law of combination in *reciprocal* and multiple, instead of in *definite* and multiple, proportions. Dr. Williamson had said of chemists that all their modes of thought, and all the government of their actions, was based upon the atomic theory; but he (Dr. Odling) maintained that it was based upon the observed fact that certain bodies combined in certain proportions. Dr. Williamson also argued that the atomic theory was based upon the existence of molecules, and that molecules had no *locus standi* in the absence of the atomic theory. He (Dr. Odling) disputed that position, for the fact that the hydrogen existing in marsh gas was divisible into four parts, and the hydrogen existing in ammonia only into three parts, was, he conceived, a fact quite independent of the atomic theory. The laws of combination, as far as they go, were compared by Sir Humphry Davy to Kepler's laws of planetary motion, which were simply a general expression of observed facts; and, in the same way, these laws of chemical combination were general expressions of observed facts upon which the atomic hypothesis was super-induced.

Professor Miller thought that Dr. Odling's arguments had not disproved the atomic theory; if they had not the atomic hypothesis, they were entitled to ask what explanation they possessed of the laws of combination? Certain facts were admitted on all hands, as determined by experiment, and when an important and extensive series of facts was ascertained, the endeavour to explain them by some supposition which embraced the facts, and which enabled them to anticipate new ones if possible, was a necessary result of their mental constitution. Unless some hypothesis were accepted, it was absolutely impossible to reason upon the facts; and if they could not adopt this hypothesis as absolutely true, such a view of the constitution of matter explained all the chemical facts that had hitherto been presented. It appeared to him that those who denied the atomic hypothesis were bound to supply something to enable them to interpret phenomena with the same regularity and order as the hypothesis, the accuracy of which they denied and desired to displace. No one would suppose that the absence of an undulatory theory for light would conduce to the explanation of optical science; and he held that what the undulatory theory was to the phenomena of light, the atomic theory was to the phenomena of chemistry.

Professor Foster thought the question before them was not so much the utility of the atomic theory as its truth. M. Naumann had stated, in his "Relations of Heat to Chemistry," that, if we assumed that in any compound body the components really occupied distinct portions of space, they must assume that body to be incapable of infinite divisibility. He thought the ideas generally entertained of the existence of the constituents of bodies in compounds were not absolutely necessary ideas. The fundamental phenomena of chemical changes might sometimes be explained by returning to the notion of the actual mutability of matter. By operating upon one portion of matter, it was actually transmuted into another, a qualitative and quantitative relation existing between the disappearing and the appearing bodies. From such ideas as these, they could not deduce the necessary existence of atoms; but all our present modes of expression and modes of thought were founded upon an atomic hypothesis or basis.

Professor Tyndall sympathised with the ideas of Professor Williamson; his thoughts had, to some extent, been expressed by Dr. Miller, who had made a strong point in referring to the undulatory theory. That theory was something super-induced upon the facts, which might be readily detached from the theory. But it was in the nature of the human mind, it was in the nature of a profound thinker, when pondering upon facts of this nature, to seek for some underlying principle outside the region of facts, from which the facts followed as consequences. Dr. Odling ought to have gone a step further than Kepler; for something that we now call "the theory of gravitation" was certainly super-induced upon his facts, as the atomic theory is upon the facts of multiple proportions. Professor Foster had justly referred to the consideration that a bad theory was very often useful. The emission theory of light was useful in the hands of Newton, Laplace, Malus, and Brewster; but this theory fell, because, in the progress of investigation, facts arose which were inexplicable by it, and which were completely explained by the undulatory theory. The undulatory theory would successfully front all opposition as long as it was competent to explain the facts of optics; and he apprehended that the atomic theory would stand as long as it was competent to explain the facts of chemistry.

Dr. Mills's conviction was that chemistry had no facts to support the notion of a limit, and the undulatory theory had an immense advantage over the atomic theory, for the existence of waves was a fact, while the existence of a limit was not a fact. It seemed to be forgotten by many writers that matter might be infinitely divisible, and yet that definite proportions might exist, for between two infinites there might be a finite ratio, so that the atomic theory was not perfectly necessary to chemistry. He believed that motion was the highest generalisation of modern science, and it therefore afforded the only criterion by which all theories, including those of chemistry, must be judged, and the notion of a limit was practically inconsistent with the idea of a motion.

Dr. Williamson, in his reply, remarked that the benefit accruing from looking at the question from another point of view would be incalculable, and if another view was developed to supersede the present one, he would be among the first to rejoice at it, but he had not to do with the future of this matter. He had endeavoured to put together the actual evidence of the present view, and none of its opponents had been able to find a fallacy in that evidence. He thought it most important to keep the theory at each period of its growth in the modest position which it at present occupies, that of generalising the best-ascertained relations of the elements in their chemical changes.

The Chairman liked to have clear and definite ideas, as far as he was able to realise them, on scientific subjects, and he was unable to consider even an atomic theory in the abstract. The atomic theory, as he understood, was —that matter is made up of finite particles, the aggregate of which could be divided and subdivided until at last only one particle would remain, and this view might be derived from the perusal and common assent of every work on Chemistry that defined the atomic theory. He thought that such a view as the physical indivisibility of matter must be separated from the facts and basis of chemistry. Dr. Williamson seemed to think the theory and facts were one, but he (the Chairman) asserted that they were two distinct things. He must also express his dissent from the views expressed by Drs. Frankland and

Miller, with reference to the use of a doctrine or theory in which they did not believe. He could not understand using a theory and denying it at the same time. This theory had, he thought, been often the means of deluding chemists into the belief that they understood things about which they knew nothing. He found the works of Kekulé and Naquèt scribbled over with pictures of molecules and atoms, combined together in all imaginable ways, for which he thought there was no adequate reason, and if there was no reason it was a mischievous thing to do. Many students, he believed, thought the pictures in Naquèt's work were chemistry; they did not draw the distinction between the facts and theory of science. His view was that the ultimate constitution of this material universe was one of those things upon which no light had yet been thrown, and he agreed with Dr. Odling when he said that the science of chemistry did not require or prove the atomic theory. They were bound to have some real and adequate means of working at the science of chemistry, and discovering its laws, and they could effect this either through the investigation of the laws of gaseous combination or the study of the capacity of bodies for heat. When they approached the science through the study of gaseous combinations, they discovered that the combining proportions of bodies were capable of being represented by integral numbers, and they also found an analogous fact in studying the capacity of bodies for heat.

The meeting was then adjourned to November 18th.

NOTICES OF BOOKS.

Nature: "*A Weekly Illustrated Journal of Science.*" MACMILLAN and Co., London.

WE are glad to notice the birth of a new popular journal of science. It was never more wanted than now, for it is undeniable that at no previous period has there been such a manifest desire on the part of the general public to understand somewhat of the great scientific discoveries and generalisations which are perpetually springing up around us. Among the objects proposed to be attained by "Nature," is the urging "the claims of science to a more general recognition in education and daily life," and we are fain to believe that there is now amongst us such a movement in this direction, emanating from diverse sources, that the time is not far distant when science will form as much a part of our own educational system as it does of that of other countries.

"Nature" appropriately opens with a series of aphorisms by Goethe; a semi-poetic composition, formed as it were, halfway between prose and poetry, in which an exalted form of prose almost merges into a regular rhythmus. Of Nature Goethe says:—"She tosses her creatures out of nothingness, and tells them not whence they came, nor whither they go. It is their business to run, she knows the road. . . . . Her crown is love. Through love alone dare we come near her. She separates all existences, and all tend to intermingle. She has isolated all things in order that all may approach one another. . . She is complete but never finished. As she works now, so can she always work. Everyone sees her in his own fashion. She hides under a thousand names and phrases and is always the same."

The principal papers are "On the recent total eclipse of the Sun" by J. Norman Lockyer, and "On the fertilisation of Winter Flowering Plants" by A. W. Bennett. There is a review of Madsen's *Antiquités Préhistorique du Danemarck*, by Sir John Lubbock, and of Newman's "British Moths," by W. S. Dallas, and other shorter notices. A paper (read at the last meeting of the British Association for the Advancement of Science), by the Rev. W. Tuckwell "On Science-teaching in Schools" contains a number of very useful suggestions, and will be read by science masters with interest. Professor Williamson furnishes an interesting life of the late Professor Graham, and we wish we could commend the accompanying portrait to a like extent. Mr. Geikie, gives an account of the meeting of German naturalists at Innsbruck. Among other features of the Journal we find several columns of "Notes," containing a chit-chat account of the matters most discussed in scientific circles at the present time. Finally, there is a *resumé* of recent work in all the more prominent branches of science, and of the proceedings of Societies and Academies. We wish "Nature" every success; it is well supervised, its contributors are manifold, and it is issued by an eminent firm of publishers. It will be a healthy sign of the times and of progress, when every educated man reads a scientific journal as regularly as he reads his "Saturday" or "Pall-mall," and to such a result the issue of "Nature" conduces.

MISCELLANEOUS.

University of London.—The following are lists of the candidates who have passed the Second B.Sc. Examination:—*Pass Examination.*—First Division. William Henry Johnson, University College; Alexander Muirhead, University College; William Stephen Ridewood, B.A., private study. Second Division. Phineas Simon Abraham, Trinity College and Royal College of Science, Dublin; William Barnett Burn (First M.B.), St. Bartholomew's Hospital; Dan Isaac Davies, private study; Septimus Peché Moore, LL.B., New and University Colleges; Frederic James Montague Page, Royal School of Mines; Frederick Antony Potter, Royal School of Mines; Charles Thomas Whitmell, St. John's and Trinity Colleges, Cambridge; William Henry Willans, University College and Royal School of Mines.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

In accordance with the generally expressed wishes of our friends and readers, we have effected arrangements to enable us to give, under the above heading, notices of EVERY CHEMICAL PAPER IN THE WORLD, *as soon as possible after publication. Whenever possible, these notices will appear in the form of carefully prepared, although necessarily brief, abstracts; as respects papers either too long or too abstruse to render condensation possible, their titles will be chronicled; and in all cases accurate reference will be made to the original publication. The two half-yearly volumes of the* CHEMICAL NEWS, *with their copious indices, will therefore be equivalent to an English edition of the "Jahresberichte," with the additional advantage of keeping the readers week by week on a level with the latest advances of science.*

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, November 2, 1869.

This number contains the following original papers and memoirs:—

Industrial Use of Mineral Oils for the Purpose of Heating Steam Boilers, and particularly Locomotive Engines.—MM. St. Claire-Deville and Dieudonné.—This paper gives an interesting account of a series of experiments made by the authors with locomotives upon the French Eastern Line (Paris to Strasbourg), with a speed of 46 kilometres (about 29 miles) per hour, and upon a portion of the line of railway which is by no means level. The consumption of mineral oil was from 3·44 to 5 kilos. per kilometre, over a total distance of 142 kilometres, run over with heavily-laden trains. The authors state that the combustion was very complete.

Heating of Wines.—M. Thenard.—This subject, which has been repeatedly before the meeting, seems to have given rise to some jealousy, as well as captious controversy. The author of this paper, acting upon the principle "*Qui bene distinguit bene docit*," states that M. Appert first discovered the principle, that M. Pasteur has given a proper scientific explanation thereof, and that, lastly, M. Vergnette has been the first man who has industrially applied this principle on the large scale with good success.

Asia Minor.—M. Tchihatcheff.—This author presents to the Academy the last, that is the eighth, volume of his great work concerning a hitherto very imperfectly known part of the globe. This volume comprises the physical geography, climatology, botany, and geology of the above-named country. The author's work is highly eulogised, and is a very valuable contribution to science.

The Chalk of Northern Europe.—M. Hébert.—A lengthy paper on an important geological formation which the author distinguishes according to the presence or absence of some animal remains into groups of different ages.

Chemical Researches of Various Combustible Gases Naturally Occurring in Central Italy.—MM. Fouqué and Gorceix.—The authors have investigated twenty-eight different kinds of gas, collected chiefly in the Appenine mountains between Modena and Imola, including four different kinds collected at the Lagoni, which yield boracic acid. As instances of the composition of these gases, we quote:—Barigazzo—CO_2, 1·58; N, 1·81; C_2H_4, 96·61. Sassuno—CO_2, 1·14; N, 0·39; C_2H_4, 80·60; C_4H_8, 17·87. Gases from the Lagoni:—Larderello—HS, 4·20; CO_2, 90·47; N, 1·90; H, 1·43; C_2H_4, 2·00. Serrazzano—HS, 6·10; CO_2, 87·90; N, 2·93; H, 2·10; C_2H_4, 0·97. This lengthy paper contains a very interesting account of the localities where the gases have been collected, and is a valuable addition to chemical geology.

A Measure which is Not Effected by Change of Temperature.—M. Soleil.—This author proposes (*risum teneatis amici*) to use beryl, the precious stone, as a suitable material for the construction of a standard measure of length, on account of its exhibiting peculiar properties on being submitted to changes of temperature, whereby it is possible that, under certain condition, it will remain invariable. Unfortunately, there are no beryls found of a metre in length, and, therefore, only a centimetre standard could be made.

Constitution and Motion of Glaciers.—MM. Grad and Dupré.—The chief results of the labours of these authors are the following:—The crystals of ice of the glaciers are arranged in a regular manner, and the constituent molecules of that ice are placed as in frozen water. The velocity of motion of a glacier increases from the bottom to the top, while the maximum of motion coincides with the greatest slope.

Heat Reflected from the Moon's Surface.—M. Baille.—According to this author, the moon's surface emits as much heat as a cube filled with boiling water, covered with lamp-black, having a surface of 6·5 square centims., and placed at a distance of 35 metres from the thermo-electric measuring apparatus employed by the author for his experiments.

Synthesis of Guanidine.—M. Bouchardat.—Four volumes of ammonia gas, and one volume of chloroxycarbonic acid, act upon each other with energy, producing chloride of ammonium and urea—

$$C_2O_2Cl_2+4NH_3=C_2H_4N_2O_2+2(NH_4Cl).$$

On repeating this experiment, the author also obtained urea, but, simultaneously, divers carbonic acid amides, and especially, also, guanidine. The author has operated with large quantities, no less than 150 litres, of chloroxycarbonic acid at the same time, and has obtained thereby:—(1) Guanidine, the sulphate of which corresponds, in composition, to the formula $S_2O_8(C_2H_5N_3)H_2O_2$. (2) Urea. (3) Melanuric acid, a white-coloured substance, insoluble in water, soluble in weak aqueous solution of caustic potassa, nitric, and hydrochloric acids; formula, $C_6H_4N_4O_4$. (4) Cyanuric acid.

On Chloral.—M. Bouchat.—During the discussion which followed the reading of this paper, it was incidentally mentioned that M. Personne, director of the chemical laboratory of the Ecole de Pharmacie, Paris, had instituted a series of experiments with chloral upon animals, with the result that chloroform was readily detected in various fluids of their bodies, after the administration of chloral.

Anti-Cholera Tissue.—M. Adeline.—This author, or rather manufacturer, having learnt that, from the experiments and experience of Dr. Burq, copper is a certain antidote against Asiatic cholera, presents samples of various woven fabrics, wherein a certain quantity of copper wire is introduced for the purpose of serving as prophylactic.

Phosphorescence of the Sea.—M. Duchemin.—According to this author, that phenomenon is due to electricity, and the infusoria only act as sharp points do in well-known electrical experiments.

Useful Application of Arsenious Acid.—Dr. Lisle.—If the statements of this physician are confirmed, arsenious acid will become a great boon to a large number of people afflicted with that most dire disease, mental derangement. According to this author, arsenious acid, properly administered, even in apparently hopeless cases, restores about 66 per cent of the afflicted to health.

Cosmos, October 30, 1869.

From this number we abstract:—

Extraction of Benzol from Coal-Gas.—M. Meunier.—All coal-gas contains the vapour of benzol, in more or less quantity. By means of cooling mixtures, pressure, and the use of some chemical reagents, as, for instance, strong nitric and sulphuric acids, chlorine, and bromine, benzol may be withdrawn, more or less completely, from coal-gas; it appears, however, that the following simple and effective plan suggested by the author, answers the purpose far better, since it is by a simple application of a solvent that the benzol is obtained:—The gas is made to pass slowly through coal oils (liquid hydrocarbons), the boiling point of which is higher than that of benzol; but it has been ascertained that petroleum, paraffin oils, schist oils, and even fixed fatty oils, will answer this purpose equally well. After a time, these fluids become saturated with benzol, and the latter is obtained by fractional distillation. It should be borne in mind, however, that gas thus deprived of benzol and its homologues loses a great deal of its illuminating power, even so much, in some instances, as to be only fit for heating purposes.

Saccharimetrical Congress at Berlin.—There has just been held at Berlin, under the presidency of the well-known Dr. Scheibler, a meeting of some twenty-five chemists, whose chief occupation is the investigation and analysis of raw sugars. The aim of these gentlemen, to fix upon a uniform method for all quantitative estimations of sugar, and thus to insure good and conformable results, has been accomplished. Special committees have been appointed to investigate everything relating to the optical saccharimetry; one of these committees undertakes to investigate thoroughly the optical power of different thin plates of quartz in reference to pure sugar; another committee, again, is engaged in the preparation of a standard sample of pure sugar, and superintending the manufacture of perfect and uniform optical saccharometers to serve as standards. A central laboratory is to be established, with branch establishments at various localities in Germany.

Temperature of the Human Body.—The average maximum temperature of adults above twenty-five years is 37·25°; below that age, 37·1°. The temperature of the human body is subject to diurnal variation—from 6 p.m. until midnight, the temperature decreases, and increases again from 3 a.m. until 9 a.m.; this variation is, on an average, 0·49°. A thermometer placed under the tongue indicates about 40°.

Guano from the Chincha Islands.—According to what the editor of *Cosmos* states to be reliable information, the quantity of Peruvian guano is so rapidly decreasing that it is no longer difficult to calculate beforehand the period at which there will be no more forthcoming. The deposit of the Guanope islets, which is, however, of inferior quality, will last for some ten years to come. After that period the Lobo Islets may yield some of this manure; but it has been ascertained that the deposit there found is relatively very poor in ammoniacal salts, and contains, moreover, very much sand.

Vulcanised Caoutchouc.—M. Mouton.—In order to give to vulcanised caoutchouc all that softness which is requisite, for instance, for printing-ink rollers, the author reduces ordinary vulcanised caoutchouc to powder, places it in suitably-shaped vessels, and submits it a second time to the temperature required for vulcanisation. By this means it is rendered soft and smooth, has entirely lost its usual harshness, and is fit for various uses—among these the making of durable printing-ink rollers.

November 6, 1869.

This number contains the following original papers:—

Description of an Oven for Burning Pottery and other Ceramic Pastes.—M. Hofmann. The contrivance here alluded to is an improvement upon those hitherto in use, which cannot be continuously used, but are only worked by interrupted periods. The furnace, or oven, here described is, in exterior appearance, somewhat like a large lime-kiln; but its interior construction consists of compartments, separated by double walls made of fire-bricks. The consumption of fuel of these ovens is stated to be small. With a circumference of 120 metres, each compartment of the contrivance alluded to is capable of containing 10,500 bricks; and about 4½ millions of bricks can be annually fired by this oven, with a saving of from 50 to 60 per cent of fuel as compared with the old methods.

Preservation of Telegraph Poles.—M. Delarge.—The preservation of the large number of wooden poles in use for carrying the conducting wires has become a very important subject. The author reviews the use of the following substances employed for the purpose:—*Sulphate of copper.*—On inspection of a large number of poles treated with this substance, it was found that, notwithstanding nearly twenty years' service, the wood was in a very excellent state of preservation; but it should be added that very much depends upon the kind of timber used for the purpose, and upon the period of the year when it is cut down. *Creosote* is very extensively applied, and, according to a series of comparative experiments, purposely instituted in Belgium, during the years 1861 and 1862, the durability of creosoted timber is considered equal to that treated with sulphate of copper. Creosote, however, is found to be, in many instances, very inconvenient, both on account of the odour it emits, and on account of the injury caused by its corrosive action upon the hands of the workmen. *Chloride of zinc.*—According to the experience of the Netherlands officers of the Waterstaat, to whom is confided the *matériel* of the telegraphic lines of that kingdom, the use of chloride of zinc has given great satisfaction in the sandy soils of Gelderland; whereas in more calcareous soils, chloride of zinc did not answer the purpose at all, a result also observed in Germany. According to the author, there is a good deal of practical experience yet to be gained in this department of chemical engineering, since every day more and more proves that the nature and qualities of the soil wherein the poles and other timber, railway sleepers, &c., are placed has a vast deal more to do with the preservation of the wood than could be, *à priori*, conjectured.

Annales des Mines, Nos. 3 and 4, 1869.

These two numbers have been issued together, and contain the following original memoirs and papers:—

Mineralogical Tabulated Form.—M. Adam.—This is a concise, but very complete and highly useful, review of the minerals, properly classified in forty-two sections, beginning with hydrogenides, and appendix on meteorites. The table indicates the crystalline shape

hardness, specific gravity, fusibility, and solubility of the various minerals, and contains, moreover, tables of equivalents of the elements and oxidised substances, with the symbols and the quantity of oxygen contained in 100 parts. We, moreover, meet here with a new method for the calculation of the relations of the elementary bodies in any analysis; this may be best explained by quoting the following:—Take, for instance, sulphur, antimony, and silver; the equivalents thereof (O=100) are—S, 200·00; Sb, 1583·00; Ag, 1350·00.

Equivalent of sulphur, $\frac{1{,}000{,}000{,}000}{200} = 50{\cdot}0000$

" antimony, $\frac{1{,}000{,}000{,}000}{1{\cdot}325} = 6{\cdot}5573$

" silver, $\frac{1{,}000{,}000{,}000}{1{\cdot}350} = 7{\cdot}4075$

A table being thus made for all elementary bodies, the multiplication by the quotients obtained, of the quantities found by weight as result of the analysis, replaces the division of these same quantities by their equivalents, and yields the same relation; for instance—

Analysis of Miargyrite.

			Rapport, or relation.
Sulphur	21·77 × 50·0000 =	108·850	4
Antimony	41·49 × 6·5573 =	27·206	1
Silver	36·74 × 7·4075 =	27·214	1
	100·00		

The division by the equivalents would have given—

$$\text{Sulphur, } \frac{21{\cdot}77}{200} = 108{\cdot}850,$$

and so on for the other elements. This memoir is a most valuable addition to mineralogy, as well as to the chemistry of minerals.

On Smoke-Coloured Quartz.—M. Commanges-Guitaud.—This paper, a letter from the French Minister, resident at Berne, contains full particulars concerning the discovery and the exploration of quartz of rare beauty, accidentally discovered in the Tiefengletscher of the valley of Urseren, Canton Uri, Switzerland. We have before had an opportunity of quoting this subject.

Use of Sewage Water in Agriculture, according to Experiments and Observations made Abroad and in France.—M. Freycinet.—This extensive memoir, filling some 130 pages, is not suitable for abstraction, but deserves the notice of all parties interested in this subject.

Mineral Resources of Algeria.—M. Ville.—This is a complete treatise on the mineral resources of Algeria, treating of the mineral fuel; iron ores; ores of copper, lead, and zinc; ores of antimony and mercury; the metallurgical works; the salt springs, salines, and deposits of rock-salt; deposits of saltpetre; quarries or layers of gypsum and alabaster; lime-stones; building-stones; brick-clay; clay fit for making pottery; slates; pouzzolanes (natural cements); sand fit for industrial use; mineral and thermal springs, divided into four groups, according to their chemical composition; and, lastly, on the success which has attended the boring for water in Algeria. This paper is an excellent monograph, and it would be highly useful if so complete a review of the mineral wealth of every European country were published.

Bibliothèque Universelle et Revue Suisse.—Archives des Sciences Physiques et Naturelles, No. 142, 1869.

This number contains no original papers relating to chemistry or allied sciences.

Moniteur Scientifique, November 1, 1869.

This number contains the following original communications:—

On So-called Iodine Green.—M. Peters.—The author of this paper states that he has thoroughly investigated this subject, and has overcome the difficulties especially attending the dyeing of wool with the green dye, now rather inaptly called iodine green. The author points out that the following advantages are obtained by his method:—(1) Woollen and mixed tissues can be dyed in a short space of time with very pure shades; (2) the colouring material is not wasted, but entirely exhausted; (3) the expense does not exceed that of the use of the so-called aldehyde green, but the iodine green is purer and faster, while shades of green, either verging upon yellow or blue, can be obtained which are not affected by artificial light. The process of dyeing is described as follows:—Impregnation bath (*bain d'impregnation*)—for bluish green, 25 kilos. of liquid iodine green, for dyeing wool, and 75 kilos. of water; for yellowish green, add 22·5 grms. of crystallised picric acid. When this mixture is brought to the boiling heat, there is placed in it a quantity of previously well washed wool which has been treated with sumac. The wool is left in the bath for about half an hour, and, on being removed, the excess of fluid is got rid of by wringing or, better yet, by the centrifugal machine. The liquid thus obtained still contains a sufficient quantity of colouring matter to be used again. The green-producing bath (*bain producteur du vert*) consists of—Water, 100 kilos.; strong sulphuric acid, 250 grms.; liquid bichloride of tin, 125 grms. This bath is used at a more or less elevated temperature, which depends, in great measure, upon the strength and quality of the tissues or yarn to be immersed therein. Instead of the liquid iodine green above alluded to, and which is not well suited for transport, the author states that, of the iodine-green paste, as met with in the trade, 10 parts have to be mixed with 200 of water; the addition of picric acid may be neglected, and, instead thereof, a small quantity of sulphuric or acetic acid should be added. Fifty parts of the fluid so obtained should be mixed with 150 parts of water; ammonia should be added, and the liquid filtered; after which it is only applicable as an impregnation bath, as above alluded to.

Prophylactic Properties of Phenic Acid.—M. Schiffmann.—The author writes from Valle-Menier, Nicaragua, Central America, stating that, after a very severe epidemic of Asiatic cholera, which caused, during fifteen months, the death of a large number of people, he commenced the use of phenic acid (carbolic acid), causing all the rooms and passages of his house and gardens to be daily watered with water to every pailful of which a tumblerful of the aforesaid acid had been added. The same plan was adopted in the cottages and gardens occupied by about three hundred people, with the result that not only no more was heard of the cholera, but there was also a cessation of intermittent fever (ague), which had almost continually pestered that locality. The author adds that he observed the extermination of all vermin, and that he also used the acid in agriculture, in order to kill noxious insects, especially ants, which abound in that clime, and do great injury to cacao trees (*Theobroma cacao*). Mixed with paint, the author applies phenic acid to wood-work, which is thus preserved from the attacks of white ants and similar vermin.

On Soaps and the Chemical Analysis thereof.—M. Joffroy.—Several methods have been at various times proposed for the quantitative estimation of the various constituents of soap. The following methods are quoted here:—50 grms. of the soap are cut up into thin shavings, and dried in a water-bath until no more loss is experienced on subsequent weighing. 12·5 grms. of the soap, cut into thin shavings, are exposed to the action of the air, in order that the free alkali present may thereby become converted into an alkaline carbonate. The sample is next dried, and afterwards dissolved in strong alcohol. In the residue insoluble therein will be found—(*a*) By means of the balance, the total quantity of free alkali (as carbonate) and other salts; (*b*) by means of neutralisation with a test-acid, the quantity of free alkalies; (*c*) by subtracting the quantity of the latter, the quantity of foreign salts will be obtained—that is to say, chlorides, sulphates, &c., of soda, potassa, and other bases. The alcoholic solution is evaporated to the consistency of a syrup, mixed with water, and decomposed by means of hydrochloric acid, whereby the fatty acids are obtained. These, after having been well washed with distilled water, are dried in a water-bath, and weighed. The aqueous solution from which the fatty acids have been separated is evaporated to dryness, ignited, and the residue weighed. This residue is chloride of sodium in the case of hard or soda soap, and, from the quantity obtained, the soda is calculated. In order to estimate the free fat, that is to say, the fat non-combined with an alkali, 10 grms. of the soap are decomposed with hydrochloric acid; the fatty matter is saponified by means of baryta, and the baryta soap obtained is treated with alcohol, whereby the unsaponified fatty matter only is dissolved. The nature of the fatty acids contained in the soap may be ascertained—that is to say, we may find whether stearic, margaric, or oleic acids predominate—by dissolving 5 grms. of the soap in water, adding to the solution enough sulphuric acid to decompose the soap, and the estimating, by means of a very sensitive thermometer, the melting point of the fatty acids; but it should be borne in mind that this operation only gives an approximate result. Another method of testing soap is the following:—Take 1 grm. of the soap, place it in a suitable vessel (a beaker glass), add ether to it, and next acetic acid in a somewhat smaller quantity. The liquid will separate, after a while, into two distinct layers, the upper of which contains in solution the fatty acids, while the lower layer contains the alkalies, and salts, and such substances as might happen to be insoluble in the two fluids just named. By means of a pipette, the fluids are separated from each other. The ethereal solution is poured into a previously weighed beaker glass, and the ether evaporated upon a water-bath, and next again weighed with the fatty acids it contains. The aqueous acetic acid fluid is evaporated to dryness, and the quantity of alkali determined according to well-known methods.

Revue Hebdomadaire de Chimie, November 4, 1869.

This number contains the following original papers:—

Apparatus for Distillation and Concentrating Liquids in Vacuo.—M. Mène.—When a closed vessel filled with steam is suddenly and efficiently cooled, this vapour is condensed, and there is produced inside that vessel a perfect vacuum, saving always the tension of the water vapour at the temperature to which it is cooled down. It is according to this principle that an apparatus has been constructed, which is illustrated by woodcuts, which are essentially necessary to the proper elucidation of the mode of action and arrangement, which is, however, so contrived as to admit of continuous action. The apparatus is made of copper, tinned inside, and is applied with great success to the extraction of the aroma of such plants and parts thereof as cannot, without deterioration of the peculiar fragrancy of the same, be submitted to the ordinary distillation process.

Tubular Germinating Machine for Malt Making.—M. Puvrez-Bourgeois.—The author begins by explaining that preliminary process of beer brewing called malting, which is generally known, although some erroneous opinions are in circulation on this subject. Grain does not, in its healthy and fully ripe state, contain any sugar at all. The process of malting is so conducted that, after the grain has been steeped in water for some hours, and has thereby become quite soft, it is placed on what are technically termed beds, and these kept together in a locality which should not be colder than from 14° to 18°. While spread out on these beds, the grain begins to germinate just as if it were sowed in soil, the radicule makes its appearance. It is necessary,

however, to supply to the grain under operation air in sufficient quantity; and, on that account, the grain has to be turned over by means of shovels. The apparatus devised by the author, and illustrated by woodcuts, is constructed with the view of receiving the grain after it has been steeped: it is put in tubes, which are closed by means of perforated lids, and can be moved by means of machinery. According to experience obtained with this apparatus on the large scale, it is highly satisfactory. The author adds one of the most recent analyses of barley, and of malt obtained therefrom. 100 parts, in dry state, contain, for barley—Dextrine, 5·6; starch, 67·0; sugar, 0; cellulose, 9·6; albumenoid substances, 12·1; fatty matter, 2·6; ash, 3·1. For malt—Dextrine, 8·0; starch, 58·1; sugar, 0·5; cellulose, 14·4; albumenoid substances, 13·6; fatty matter, 2·2; ash, 3·2. During the subsequent mashing process, a large proportion of the dextrine is converted into sugar, and the starch into dextrine. The malt here alluded to is the so-called pale, that is, air-dried, malt.

Composition of Different Kinds of Porcelain.—M. Moron.—The materials used for the manufacture of porcelain vary, as will be seen, considerably. At Nymphenburg, Bavaria, the mass is made up of:—Kaolin from Passau, 65 parts; fine white sand, 4 parts; quartz, 21 parts; gypsum, 5 parts; broken-up biscuit, 5 parts. Vienna:—Kaolin from Zedlitz, 34 parts; kaolin from Passau, 25 parts; kaolin from Unghvar, 6 parts; quartz, 14 parts; felspar, 6 parts; metal (broken and ground-up china), 3 parts. Meissen, Saxon-Prussia:—Kaolin from Aue, 18 parts; kaolin from Sosa, 18 parts; kaolin from Seilitz, 36 parts; felspar, 26 parts; metal, 2 parts. The mixture of materials used at Sèvres is only known to those who have the management of that famous manufactory: the kaolin chiefly comes from St. Yrieux.

Pharmaceutische Zeitschrift für Russland, September, 1869.

This number contains the following original papers and communications:—

Monograph on Inuline.—M. Dragendorff.—This lengthy and exhaustive memoir is a compilation embracing everything relating to this subject. The paper is too lengthy to admit of suitable abstraction.

Chloroform, and its Behaviour towards Light and Air.—M. Hager.—The author made a series of researches with commercial chloroform obtained from a firm dealing wholesale in this article. The author's paper is divided into the following sections:—Chloroform of commerce contains, besides real formyl-chloride, other chlorinated compounds, which are not readily separated therefrom.—This is proved by the fact that, after the separation of alcohol and water, which are invariably present in all commercial chloroform, a fluid is obtained which begins to boil at from 60° to 61°, and at the end of the distillation boils at 65°. By repeated fractional distillation, it is possible to obtain pure chloroform, which can only be properly tested for by means of its boiling point and specific gravity. Pure chloroform is not decomposed by the action of light only.—When chloroform is exposed to the direct action of the sun's rays, it becomes decomposed, exhibits an acid reaction to test-paper, and there are found, among its products of decomposition, hydrochloric acid, chloroxycarbonic acid, formic acid, and free chlorine. Chloroform is decomposed when air has access to it, even in the dark, although only slowly.—A quantity of from 0·75 to 1 per cent of alcohol added to chloroform is sufficient to act as a preservative for keeping chloroform for years, even when exposed to daylight. Chloroform, even if it does not exhibit an acid reaction, may be in a state of decomposition.—This decomposition can only be detected by the reaction such chloroform exhibits with ammonia, which then yields with it vapours of chloride of ammonium. The cause and products of this decomposition are not ascertained. The boiling point and specific gravity of chloroform are variously determined by different authors:—The *Pharm. Austriaca*.—Boiling point, 63·5°; sp. gr., 1·49 to 1·5. Dr. Strecker—Boiling point, 61°. M. Limpricht—Boiling point, 62°. M. Bilts—Boiling point, 62·05°. Specific gravity—At 10·2°=1·5085; at 15°=1·5020; at 17·75°=1·4971; at 20·0°=1·4936.

Action of Iodine upon Arseniuretted and Antimoniuretted Hydrogen.—Dr. Husson.—The author finds that both these gases, when made to pass over iodine, readily yield iodides of arsenic and antimony. The author further suggests that this reaction should be made use of in toxicological investigations. For this purpose, when Marsh's apparatus is used, a small quantity of iodine should be placed in that portion of the tube where, commonly, the metallic mirror is made apparent; that part of the tube is gently warmed, so that the iodine coats the tube; and the gas is then made to pass, care being taken to keep the tube somewhat warm. Should the gas contain arsenic, a yellow-coloured mirror will be at once observed; when the gas contains antimony, an orange-coloured iodide of that metal is formed. The iodide of arsenic yields, when volatilised, yellow-coloured vapours, while the vapours of iodide of antimony are of a deep red hue.

Les Mondes, November 4, 1869.

We learn from this journal that M. Wurtz, the well-known scientific chemist, and Dean of the Medical Faculty of Paris, has been nominated Commander of the Order of the Legion of Honour. Among the number of scientific men who have been decorated as chevaliers of the same order, we meet with the names of MM. Schutzenberger, Friedel, and other well-known scientific men.

Navigation on Canals.—M. Bouquié.—Although this short notice does not exactly belong to the sciences usually treated of in our pages, we cannot refrain from quoting the following curiosity:—The distance from Mons (Belgium) to Paris, by canal, is 350 kilometres. The distance from Cardiff to Singapore is 25,000 kilometres; yet the journeys from Mons to Paris are performed by canal so slowly, that the journey from Cardiff to Singapore, if performed at the same rate of speed, would occupy eleven years. The coal-laden barges sailing between Mons and Paris make only three journeys during a whole year.

Manufacture of Manganate of Lime.—M. Delaurier.—Manganate of lime, CaO,MnO_2, can be directly obtained by heating together any oxide of manganese, previously reduced to powder, and mixed with slaked lime or chalk in equivalent proportions. The two substances should be intimately mixed, and heated to redness, with contact of air and constant stirring of the mixture, in order to promote the absorption of oxygen. This compound is insoluble in water; it is far more readily prepared than the manganates of soda and potassa, because these are fusible, and, hence, less manageable during the process. The manganate of lime yields oxygen on being heated by itself; and, when treated with sufficient sulphuric acid to convert the lime and manganese into sulphates, two equivalents of oxygen are given off. The waste manganese salts obtained in various manufacturing processes may be usefully applied to the preparation of the manganate of lime.

Apparatus for the Demonstration of the Fall of Bodies.—M. l'Abbé Vassart.

Boiling Point of Water at Localities the Height of which Above Sea Level has been Correctly Determined.—M. Ziurek.—The heights are expressed in metres, the average reading of the barometer at each locality in millimetres, the boiling point in °C. The highest inhabited spot on the globe is the township of Antisana, Peru (4101 metres above sea level)—Barometer, 454; boiling point, 86·3°. City of Quito (2908 metres)—Barom., 527; b.p., 90·1°. Santa Fé de Bogota (2661 metres)—Barom., 5·44; b.p., 90·9°. City of Mexico (2270 metres)—Barom., 5·72; b.p., 92·3°. Hospice du St. Gothard, Switzerland, the highest inhabited locality in Europe (2075 metres)—Barom., 586; b.p., 92·9°. Gavarni, France (1444 metres)—Barom., 634; b.p., 95·0°. St. Ildefonse Palace, Spain (1155 metres)—Barom., 657; b.p., 96·0°. Madrid (608 metres)—Barom., 704; b.p., 97·8°. Munich, Bavaria (538 metres)—Barom., 710; b.p., 98·1°. Moscow (300 metres)—Barom., 732; b.p., 99·0°. Rome (46 metres)—Barom., 756; b.p., 99·8°. Berlin (40 metres)—Barom., 756; b.p., 99·8°. As regards London, the enormous size of this province of houses makes it impossible to define, for that great extent, any average. Those portions nearest to the river are no more than about from 3 to 5 metres above sea level (not to be mistaken for what is locally known as Trinity high-water mark), while the more elevated portions are some 30 to 40 metres above the same level.

NOTES AND QUERIES.

By-Products Containing Soluble Phosphates.—Will any of your correspondents give information as to where any by-products can be obtained containing 3 per cent and over of soluble phosphate?—ARTHUR WARNER.

Preventing Moisture in Glass Cases.—Wishing to enclose a philosophical instrument in a second outer case of glass, where moisture is an enemy, can any correspondent inform me which is the best material to use, chloride of calcium, quicklime, $HO+SO_3$ dehydrated alcohol, or a small stick of sodium (to be scraped occasionally)?—S. E. P.

Standard Verification.—Having to deal with 1-1000ths of an inch, and having a friend who has to deal with 1-10,000ths of an inch, and finding a deplorable ignorance among the skilled artisans of London and an awful discrepancy with expensive gauges by Holtzaffel's, Elliott, and others, can any correspondent guide me to any system of standard verification? Outside the Greenwich observatory may be seen a standard of feet, inches, and moderate subdivisions. Is there any inner department for finer minutiæ available for the public?—S. E. P.

MEETINGS FOR THE WEEK.

THURSDAY, 18th.—Chemical, 8. Prof. Church, "On Namaqualite," and "Chemical Researches on New and Rare Cornish Minerals (No. 6)—A New Ferric Silicate." Dr. Stenhouse, "On Chloranil and Bromanil (No. 2)"

TO CORRESPONDENTS.

J. and E. Sturge.—Apply to Asher and Co., Foreign Booksellers, Bedford Street, Covent Garden.

THE CHEMICAL NEWS.

VOL. XX. No. 521.

FLUX FOR BLOWPIPE ANALYSIS.

By Professor HOW, D.C.L., Windsor, Nova Scotia.

UNDER the heading given above, the CHEMICAL NEWS last year (vol. xviii., p. 203) reprinted a note by Mr. S. D. Poole to the *Scientific American* on the advantages of a mixture of selenite and fluor over the well-known flux of bisulphate of potassium and fluor devised by Turner as a reagent for producing coloured flames before the blowpipe, and over selenite alone as an addition to silicates, recommended by Fresenius. Mr. Poole's objection to the former is the intense violet tint given to the flame by potassium, and to the latter, its infusibility and want of decomposing power. This reagent, he says, "forms an easily fusible bead, which by itself gives only a very faint dull red tint (lime) to the flame, but which renders the presence of such elements as give colour most beautifully evident and characteristic."

My present object is to point out that the newly proposed flux is of more limited applicability than that of Turner, because there is no provision in it for the liberation of hydrofluoric acid. In testing for boracic acid *e.g.*, it fails completely to give the green flame with natroborocalcite and with borax, whereas Turner's flux gives a distinct reaction in each case. When silica is present in minerals along with much boracic acid, the addition of either of these fluxes is superfluous; thus with silicoboro-calcite a fine green—not yellowish green—is obtained with the mineral alone. Sussexite gives a yellowish green colour alone, and the addition of Poole's flux seems to me to obscure the reaction, while Turner's gives a fine green flame. As regards some other colouring elements, when colour is given by minerals alone, the best colour is obtained without the new flux; this is the case with celestine and strontianite. When silica is present, the test answers well in some instances, as with lepidolite and spodumene, and especially, as Mr. Poole states, with the felspars in which K and Na exist alone or predominate respectively. I may mention that small quantities of boracic acid which escape detection by using even Turner's flux, may be discovered in minerals soluble in HCl by repeated wetting and drying of the turmeric paper.

SUPERSATURATION, SURFUSION, AND SOLUTION.

By M. DUBRUNFAUT.

SUPERSATURATION is evidently a badly-defined phenomenon of solution; and a study of these phenomena is the only way of ascertaining the cause of supersaturation.

The interesting labours of M. Gernez, animated by the beautiful experiments of M. Pasteur, have established, in the most complete manner, the active part invariably played by the crystal which causes a cessation of the state of supersaturation in similar or isomorphous crystals. This proves the existence of a special power in the crystals themselves, varying in its mode of being according to their chemical and geometrical formation. But the labours of M. Gernez end here; they show, in fact, in the case of sulphate of soda, for instance, the generalisation of the long-known property possessed by a crystal of sulphate of soda of causing a supersaturated solution of the same salt to instantly assume the form of a crystalline mass. Nothing, however, of the cause of this fact, or of its relation with the condition of supersaturation, has been explained.

M. Loewel has fully proved, with regard to the supersaturation of sulphate of soda,* that the salt dissolved as the compound $SO_3NaO.10HO$ is found in solution in the state of $SO_3NaO.7HO$. The experimental demonstration of this fact appears to be the result of the exact analysis of crystals formed simply by lowering the temperature of the supersaturated liquid. The dissolved salt which is thus brought into a state of supersaturation changes its nature, or, at least, its molecular constitution. It now becomes a totally different product, possessing other properties, and that which is considered as supersaturation of the primitive product is really, in the new substance derived from it, merely a normal saturation; in other words, sulphate of soda is dissolved in water in the proportion of 10 equivalents of the latter, and, upon overcharging the solution with an excess of the salt, its composition is modified in such a manner as to create a new and more soluble product, consequently susceptible of producing that apparently strange phenomenon called supersaturation.

This interpretation of the facts relating to supersaturation does not detract the rules of the experimental method; and, by developing its logical consequences, the theory may be generalised and applied to all cases of solution, even to those not possessing the characteristic properties of supersaturation.

If it be certain (as we admit) that the sulphate of soda, with 10 equivalents of water, exists in the so-called supersaturated solution, with the molecular composition characterised by 7 equivalents HO, it is none the less true that, under certain known conditions, the composition of the salt may return to its primitive condition, which clearly proves, in the dissolved sulphate of soda, an unstable and fugitive molecular condition, which any accident or untoward circumstance may alter or destroy. This is what happens, in fact, under the influence of a crystal similar to sulphate of soda with 10 equivalents of water, or of an isomorphous salt; and, in this case, the return of the salt to its primitive composition is accompanied by a thermic manifestation, which confirms the change, such as may be noticed in amorphous allotropic changes, and in those of substances which crystallise in two shapes.

The modifications which matter presents in solution are confirmed, under another form, by the fact of double molecular rotation, which has been observed in crystalisable glucose, lactine, and their derivatives. In these cases, the crystallisable substances evidently contract the molecular constitution which they display at the moment of solution from the power of crystallisation, and it lasts sufficiently long to be quite perceptible. In the case of crystallised glucose, the transition of bi-rotatory to the state of monorotatory glucose requires, at a low temperature, four or five hours for completion.

This property is not perceptible in all molecularly-active substances, but it is believed to be general and proper, not only to all substances possessing the molecular property, but to all soluble substances whatsoever.

It is, therefore, highly probable that all soluble, crystallisable, or amorphous bodies have, when in solution, a different molecular constitution to that possessed by them when in a solid condition. This modification, as is proved by supersaturation and double rotation of glucose, is only ephemeral, and depends upon the particular condition of the substance in solution, and perhaps, also, on the nature of the solvents; it ceases when the causes which produce it are removed.

* M. Gernez, who has studied this subject with care, attributes the priority of the observations in question to foreign observers; but M. Loewel has also worked them out in a much better manner, without having previously heard of them, and therefore deserves the credit of an original discovery.

Thus it is retained by crystallised glucose in its crystalline state, whether its constitution be $C_{12}H_{12}O_{12}$ or $C_{12}H_{14}O_{14}$; but the moment that the crystal becomes liquefied, either by melting or by any kind of solvent, its molecular constitution, displayed by its rotatory power, is changed, and can only be regained by a return to the solid condition. Thus all known facts relating to supersaturation and surfusion may be explained without the necessity of distinguishing these different conditions of matter by the physical causes which annul them.

Solution, regarded thus, enters into the category of known chemical forces, which modify, in a regular and invariable manner, the arrangement of elements in integrant molecules.

After a careful examination of osmotic analysis as applied to complex saline solutions, I find that it is impossible to agree that diffusibility, which is, as we have demonstrated, the vehicle of this mode of analysis, occurs when the substance in question is in a solid state; on the contrary, everything goes to prove that the elements of the current of exosmose which produce the analysis are derived from a fraction of the solvent charged with the diffusible product. If this were not so, it would be difficult to account for what passes in my methodical analysis of molasses, in which the diffusion of sugar is constant at every period of the analysis, whilst the diffusion decreases geometrically in proportion as the analysis reaches its termination.

It certainly must be admitted that, in a solution of sundry salts, possessing different physical and chemical properties, each salt takes and retains, even in the complex solution itself, that contingent of the solvent assigned to it by its special qualities. It is upon these molecular liquid groups, which are more or less defined in every medium, that the force of diffusion is exercised which acts in so evident a manner in all cases of endosmotic analysis.

Here is another important fact in molecular physics which has been confounded by experimentalists with those of supersaturation.

When a crystallisable substance, such as sugar, is extracted from its solution in water by very strong alcohol, two different cases may arise, according to the conditions of the experiment, in which the sugar remains for a moment in a state resembling the phenomenon known as supersaturation, but which really differs from it essentially, or the sugar is precipitated in viscous lumps resembling precipitates formed under the same conditions by gum, dextrine, &c.

Upon examining this precipitate with a microscope, an amorphous or globular texture is easily observed, and these products float in the alcoholic solution. After a certain time, the viscous precipitate is transformed into well-defined prismatic crystals of sugar. These facts appear frequently, if not always, under the experimental conditions specified by M. Margueritte—to separate sugar from molasses by means of alcohol and sulphuric acid. This effect has been confounded with the known phenomenon of supersaturation. Under these conditions, alcoholic solutions said to be exclusively supersaturated furnish their contingent of sugar without change of density, which proves that all the sugar obtained was the result of amorphous sugar. Is not this transitory state of the sugar shown by the action of the alcohol on the dissolved sugar, the normal condition of sugar modified by solution? and is not this experiment a fresh proof in support of my mode of considering the phenomena of solution and supersaturation?

Is not that particular state of matter to which Mr. Graham has given the name of *the colloid condition*, a transitory and ephemeral condition analogous to that to which I have just called attention with regard to crystallisable sugar, and which is common to a number of other substances soluble and crystallisable from alcohol?—*Comptes Rendus.*

MODIFICATION OF THE METHODS FOR THE

VOLUMETRICAL ESTIMATION

OF THE

QUANTITY OF COPPER AND ZINC CONTAINED IN ORES

BY MEANS OF A STANDARD SOLUTION OF FERROCYANIDE OF POTASSIUM.

By M. MAURIZIO GALETTI,
Chief Assayer and Chemist of the Royal Assay Office at Genoa.

WHEN the ores of copper or zinc, after having been acted upon by acids, are treated with excess of ammonia in order to precipitate the oxide of iron, that substance invariably retains larger or smaller quantities of the oxides of the metals just named. The quantity thereof so retained varies according to the larger or smaller quantity of copper and zinc contained in the ores. It is hence necessary to repeat the treatment with ammonia at least twice, sometimes even three and four times, in order to obtain a complete separation of copper or zinc from the iron.

In order to obviate the loss of time which is caused by these operations, the author proposes to convert into acetates the small quantities of the oxides of copper and zinc which accompany the precipitate of oxide of iron. This can effected by two different methods, dependent on the fact whether the oxide of iron is removed by filtration (previous to the use of standard solution of ferrocyanide of potassium), or is left in the ammoniacal liquid. The operation is conducted as follows.

Suppose a copper pyrites to be submitted to analysis. Take 1 grm. of the previously very carefully pulverised and dried ore. Treat it first with concentrated nitric acid, boiling to incipient dryness, in order thereby to free the sulphur from any small particles of ore which at are first taken up by it. Add 10 c.c. of hydrochloric acid, boil down to about half that bulk, dilute with distilled water, and next add ammonia in large excess; boil the fluid, and next add pure acetic acid (sp. gr., 1·070) until the liquid assumes an emerald-green colour. After the liquid has been well stirred up, boil again for about two minutes; then add again ammonia in excess. The liquid is then poured out of the flask into a suitable glass vessel, and the flask is rinsed out with a sufficient quantity of distilled water to bring the bulk of the fluid up to ½ litre. This having been done, the fluid is very cautiously and gradually acidified with very dilute acetic acid, 1 part of the acid just alluded to, and 10 parts of distilled water. Any large excess of this acid should be avoided; the fluid should only be very slightly acid. As soon as the basic acetate of iron has subsided, the precipitation of the copper by means of the standard solution of ferrocyanide of potassium is proceeded with.

Since the oxide of copper which might have adhered to the oxide of iron has been converted by the process just described into a soluble salt, it cannot fail to be completely precipitated by the ferrocyanide of potassium solution. When a determination of copper has to be made in ores which are rather poor (that is to say, contain less than, or up to, 6 per cent of copper), it is preferable to add to the nitric acid solution 0·1 grm. of pure copper, which quantity has to be deducted afterwards from the results obtained. This precaution is required in order to prevent the presence of a large quantity of oxide of iron from vitiating the results of analysis of poor ores. When ores contain up to 12 per cent of copper, a quantity of 1 grm. of the ore should be taken; but, for richer ores, 0·5 grm. is sufficient. It is always advisable to make a control analysis with pure copper at the same time while testing the ores.

The second modification is carried out in the following manner.

After the second addition of ammonia to the liquid, it is filtered, and the precipitate is washed with a dilute and

boiling solution of acid acetate of ammonia. This solution is prepared by saturating 20 grms. of pure acetic acid with ammonia, and addition thereto of 15 grms. of pure acetic acid in 585 grms. of water. When the washing of the oxide of iron is carefully done, the salt of copper, which tenaciously adheres to the oxide of iron, is entirely removed therefrom; but it will require about 400 grms. of the fluid, the preparation of which has just been described.

The normal solution of copper should be treated as follows.

A quantity of 0·2 grm. of pure copper is dissolved in nitric acid; excess of ammonia is added; the fluid next acidified with acetic acid, thereupon diluted with 400 grms. of acid acetate of ammonia, and the whole brought up to 500 grms. To this solution 20 c.c. of the standard solution of ferrocyanide of potassium are added, and, after the necessary corrections have been made, the liquid must not contain any more excess of either copper or of ferrocyanide.

The standard solution of ferrocyanide of potassium to be used for the determination of copper is made by dissolving 50·225 grms. of ferrocyanide in as much distilled water as will suffice to make the solution weigh exactly 1 kilogramme.

The ferrocyanide solution destined for the estimation of zinc is made by dissolving 41·250 grms. of the said salt in the same quantity of water.

If it should happen that the copper ores contain zinc, nickel, and cobalt, the copper should be first separated from these metals, either by precipitating the copper from its solution in acid by means of zinc, or as sulphide of copper by means of hyposulphite of soda.

Zinc ores are treated in the very same manner as just described for copper ores. When sulphuret of zinc (the "black-jack" of English miners) is to be operated upon, care should be taken that, after the addition of hydrochloric acid, the fluid should be sufficiently far evaporated as to insure the expulsion of all nitric acid. Since zinc ores are usually rather rich, ½ grm. is sufficient for analysis. Calamine-stone (native carbonate of zinc) should at once be acted upon with hydrochloric acid; but, in order to make sure of the complete oxidation of all the iron the ore may happen to contain, it is best to add to the acid a few decigrammes of pure chlorate of potassa. After having suffered this solution to boil for a few minutes, it is diluted with distilled water; a large excess of ammonia is added to the solution, and it is next treated as above-described for copper.

The author states that he has convinced himself, by a set of experiments instituted on purpose, that the presence of compounds of lead (as, for instance, carbonate, sulphate, and sulphide of lead) occurring along with the ores of zinc, does not interfere with the correctness of the complete precipitation of zinc as ferrocyanide of zinc. This even holds good up to 10 per cent of metallic lead, a quantity which does not, also, interfere when mixed with copper ores.

Since some ores of zinc, especially calamine-stone, may, and often do, contain manganese, it is best to add to the ammoniacal solution, before any acetic acid is added, a few drops (from 2 to 4) of bromine, in order to convert thereby the protoxide of manganese into protosesquioxide, leaving the solution standing for twenty-four hours after the addition of the bromine.

Since the ammoniacal solution of chloride of zinc is colourless, there should be added to it, previous to the very cautious acidification by means of dilute acetic acid, a few drops of tincture of litmus, in order to more readily hit the precise point of sufficient acidification, to be exhibited by the blue colouration changing to a rose-red.

When iron is present, the same precautions are to be observed as described under copper.

The ferrocyanide of zinc which is mixed with oxide of iron preserves its naturally-white colour as long as the liquid yet contains free zinc, but its colour changes to a greyish white as soon as a very slight excess of the ferrocyanide standard solution is present; the liquid then also becomes turbid, and the precipitate settles very slowly. By these constantly-occurring and quite characteristic signs, the end of the operation may be always recognised. In order to make sure, the liquid should be stirred up with a glass rod which has been just previously moistened with an acidified and dilute solution of ammoniacal nitrate of copper, which will have the effect of indicating any excess of the ferrocyanide solution, by exhibiting the more or less intense colour characteristic of ferrocyanide of copper. The zinc solution should be at a temperature of from 40° to 50°, whereby the rapid precipitation and subsidence of the ferrocyanide of zinc is promoted.

When filtration is avoided, the presence of the gelatinous silica (due to the decomposition of silicates of zinc occurring in the ores of that metal, and brought to a gelatinous condition by the treatment of such ores with hydrochloric acid) does not interfere with the correctness and good results of this method of estimating zinc quantitatively in its ores.

It is gratifying to learn that, since the discovery of extensive and very valuable zinc ore deposits (calamine-stone) in the island of Sardinia, and the demand for this ore created in England, France, Belgium, and Rhenish Prussia, a committee of analytical chemists from these countries have, after having previously made themselves fully acquainted with the method of analysis of zinc ores just described, unanimously resolved to estimate the zinc (to be brought under contract to each of the countries just named from Sardinia) by the method here described, as being the best suited for the purpose.—*Zeitschrift für Analytische Chemie.*

ON MICROSCOPICAL MANIPULATION.*

By W. T. SUFFOLK, F.R.M.S.

(Continued from p. 233.)

MANY other saline solutions will be found in microscopical works. The best have been given above; a larger selection would tend rather to confuse than assist the beginner.

Glycerine is one of the most valuable materials ever added to the resources of the microscopist. We are indebted to the late Mr. Robert Warington for the application of this fluid to microscopical purposes. It is obtained as a waste product in the manufacture of soap, and lead plaster. The quality of the glycerine from these sources is very inferior, being both weak and impure. The best is that made by Price's Patent Candle Company, and obtained by a distillation process. This is much purer and stronger than the common kind, having a specific gravity of about 1240, and is the only kind fit for use by the microscopist. The properties of glycerine as a means of giving transparency to an object have already been mentioned. It is a thick, syrupy, and highly refractive fluid, nearly colourless, and intensely but pleasantly sweet. Although made from fat, it is not at all greasy, but freely miscible with water and many other fluids; it is also a solvent for a great number of substances. Its action upon varnish has already been alluded to. It is stated by Dr. Carpenter that it dissolves carbonate of lime readily, and quite destroyed the calcareous skeleton of certain *Echinodermata* mounted in it. He suggests that, when used for such purposes, it should be saturated with carbonate of lime

* The substance of a course of lectures delivered to the members of the Quekett Microscopical Club, January—April, 1869.

by being kept in a bottle with some fragments of marble ("Microscope and its Revelations," fourth edition, p. 222). One of the advantages of glycerine is that it never dries; so that an object can be placed in it, covered with a glass, and left uncemented, without fear of evaporation for any length of time, and afterwards mounted permanently, if desired. Owing to its free miscibility with other substances, it forms many very valuable compounds, some of which will presently be described. A very full account of its use in delicate physiological investigations is given in Dr. Beale's "How to Work with the Microscope," a book of the greatest service to all intending to study the particular subjects upon which it treats. It is by the use of glycerine that Dr. Beale has succeeded in carrying on his elaborate investigations of the ultimate structure of nerve tissue under excessively high powers; and his processes afford a remarkable illustration of the support afforded to a delicate tissue by immersion in a fluid of extreme density, the manipulation of tender substances being comparatively easy in glycerine, when, in water or alcohol, it would have been impossible.

Strong glycerine preserves nearly every kind of object, whether animal or vegetable, with great perfection, and is, perhaps, the nearest approach to an universal mounting-fluid yet known. Insects and other objects may be put into a bottle of glycerine, and left until wanted; they are even better after a year or two's soaking. Objects mounted in glycerine generally improve after a time, details often being visible which were not seen immediately after mounting. The introduction of the binocular microscope has very much influenced the style of mounting objects to be viewed with low and medium powers. For this purpose, it will be found advantageous to mount the object with little or no compression. Of course, for examination with high powers, thin and compressed specimens are absolutely necessary (see author's paper, *Monthly Microscopical Journal*, vol. i., p. 331).

Glycerine can be diluted to any extent, either with camphor or creosote water, should it be desired to obtain a less refractive fluid, and one which does not render objects so transparent as pure glycerine; sometimes a portion of alcohol may be added with advantage. This compounding of media is one of the greatest arts in fluid mounting, and can only be acquired by experience, as, at present, no definite directions can be given. Diluted fluids, as a general rule, make animal tissues more granulous and opaque after a time than the strong, dense ones. The author possesses an instance of a difficult mounting accomplished almost by chance. The subject was the Medusoid embryo of *Hydra tuba*, which he had been observing at a friend's house. Thinking it a pity to lose a specimen then seen for the first time, he took the object home alive in its cell of sea-water, and then determined to attempt its permanent preservation. The course of operation was as follows:—The slide was placed in a saucer, which was quickly filled with strong alcohol (about 60 over proof). This fortunately killed the animal so suddenly that it was but little contracted. A mounting-fluid, consisting of glycerine, alcohol, and sea-water, was then extemporised, and the object mounted. It is still in good preservation, although somewhat opaque. It was mounted in February, 1862. This is given as an instance of the kind of practice occasionally needed in cases of emergency, and where the tact acquired by experience may be turned to good account.

It is occasionally convenient to make use of a medium which, while it is fluid at the time the object is mounted, will ultimately harden, and preserve the object from injury from being shaken or moved. Such media are especially useful for mounting *Diatomaceæ* attached to other *Algæ*. There are many compounds of this nature, some of the best of which are largely composed of glycerine.

The earliest of these was that known as *Deane's gelatine*. It is composed of—Gelatine, 1 oz.; water, 4 ozs.; honey, 5 ozs.; creosote, 6 drops; alcohol, ½ oz. The gelatine is to be soaked in the water until quite soft; the honey, heated to the boiling point, is to be added. The whole is then to be boiled, and, when it has cooled a little, the creosote and alcohol, mixed together, are to be added, and the whole filtered through fine flannel.

Glycerine jelly consists of gelatine soaked in camphor-water until it swells and becomes soft. The surplus water is to be poured off, and the jelly strained, and, if necessary, clarified after the manner of confectioners with white of egg. To every ounce by measure of this jelly add 1 drachm of alcohol and 6 drachms of Price's glycerine.

Both these media are used by melting the composition by placing the bottle in hot water, just as glue is melted. It is then used almost precisely in the same way as Canada balsam, taking the precaution to prepare the object by a previous soaking. Thin objects do not require a cell. When the gelatine has hardened sufficiently, the surplus portion is scraped off, and the slide cleaned. It should then be secured with a coat or two of liquid-glue, followed by several coats of gold-size, as in moist preparations.

A very useful medium of nearly similar properties is made according to the following formula of Mr. Farrants:—Picked gum arabic, 4 parts by weight; water, 4 parts; glycerine, 2 parts. The mixture is to be made cold, and, if necessary, strained through fine muslin. It is to be used in the same manner as the foregoing gelatinous preparations, only without heat, which renders it particularly fit for objects that will not bear the slight increase of temperature required to liquefy gelatine.

The action of all the above media is nearly similar to that of slightly diluted glycerine, excepting that, when set, they keep the object fixed in the position in which it was mounted.

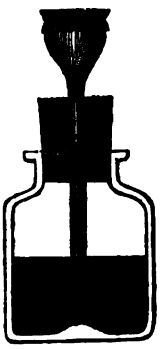
Strong syrup is capable of preserving animal and vegetable tissues, but is, under some conditions, liable to crystallise. The best proof of the perfect manner in which vegetable substances are preserved is given in the condition of preserved fruits, which are in an extremely favourable condition for microscopical examination. The samples of jam, &c., examined by Dr. Hassall, and reported upon in his "Food and its Adulterations," were probably among the tissues most easily identified, owing to their perfect condition.

Castor-oil will be found an excellent mounting-fluid; it penetrates, and gives considerable transparency, and keeps the object well and for a long period. It is particularly successful with parasitic insects; these may be placed in a bottle of castor-oil, and kept until required for mounting. As castor-oil is so readily procured, being in every medicine-chest, and to be obtained at any little village shop, it is a very useful medium for those who may wish to pre-

serve insects, &c., captured while travelling, as they need no attention after they are immersed in it. Should it be desired to mount the objects ultimately in some other medium, the oil can easily be removed by soaking in benzol.

Mounting-fluids which are in frequent use are best kept in a small, wide-mouthed bottle, through the cork of which is passed a pipette, surmounted by a funnel at its upper extremity, upon which is stretched a piece of sheet india-rubber (Fig. 18). By this

FIG. 18.



contrivance, a small quantity of fluid can be taken up, and delivered, drop by drop, upon the slide. Where mounting-fluids are continually required, as in pathological laboratories, Dr. Beale has contrived a little fountain on the principle of the wash-bottle, which answers admirably for a supply of any kind of fluid in drops; but, for the occasional use of the student, the pipette-bottle is to be preferred.

Closely connected with fluid mounting is the process of staining tissues. This is used for two widely different purposes. The first for rendering very transparent bodies more easily visible; this is easily done by immersion in magenta, diluted as the particular case may require. The other for more clearly defining certain parts, or parts in a particular state; this is done by using staining fluids which act unequally. For instance, if it be desired to stain the nuclei of cells, the following solution of carmine, described by Dr. Beale in "How to Work with the Microscope," and reprinted here by his kind permission, will answer admirably:—"Carmine, 10 grains; strong liquor ammoniæ, ½ drachm; Price's glycerine, 2 ozs.; distilled water, 2 ozs.; alcohol, ½ oz. The carmine, in small fragments, is to be placed in a test-tube, and the ammonia added to it. By agitation, and with the aid of the heat of a spirit lamp, the carmine is soon dissolved. The ammoniacal solution is to be boiled for a few seconds, and then allowed to cool. After the lapse of an hour, much of the excess of ammonia will have escaped. The glycerine and water may then be added, and the whole passed through a filter or allowed to stand for some time, and the perfectly clear supernatant fluid poured off and kept for use. This solution will keep for months, but sometimes a little carmine is deposited, owing to the escape of ammonia, in which case one or two drops of liquor ammoniæ to four ounces of solution may be added." For further information relative to the application of the staining process, and the observations to be carried out by its means, the student is referred to Dr. Beale's work.

Solutions of chloride of gold and nitrate of silver may also be employed to advantage (see paper by Dr. Bastian before quoted; T. Dwight, *Monthly Microscopical Journal*, vol. ii., p. 45).

(To be continued).

ON A NEW CHROMIUM OXYCHLORIDE.*

By T. E. THORPE, Ph.D.,
Assistant in the Laboratory of Owen's College.

WHEN chromyl dichloride $CrO_2\left\{\begin{matrix}Cl.\\Cl.\end{matrix}\right.$ prepared by heating a mixture of potassium dichromate, sodium chloride, and sulphuric acid, is maintained at a temperature of 180° C. —190° C. in a sealed tube for three or four hours, it is almost completely converted into a black solid substance, and on opening the tube when cold a considerable quantity of free chlorine escapes. By exhausting the tubes containing the liquid chloride before subjecting them to heat, I have ascertained that chlorine is the only gaseous product of this decomposition. The black compound invariably contains more or less of the liquid chlorine which has escaped decomposition: the greater part of this is easily expelled on gently heating the mass after opening the tube. In order to free it completely from the latter body, the black substance was transferred to a clean tube and heated to 120° C. (*i.e.*, about 2° above the boiling point of chromyl dichloride) in a current of dry carbonic acid gas until its weight appeared constant. The following determination of the amount of chlorine contained in the volatile portion shows that it is simply chromyl dichloride which has remained undecomposed.

0·8741 grm. liquid chloride gave 1·6458 grms. silver chloride.

Calculated for CrO_2Cl_2.	Found.
45·7 per cent.	46·5 per cent.

The solid substance dried in the manner above described appears as a black uncrystalline powder, which when exposed to the air rapidly deliquesces to a dark reddish brown syrupy liquid which smells of free chlorine. When thrown into water it quickly dissolves, forming a dark brown solution, which on standing also evolves chlorine. In nitric acid solution hypochlorous acid appears to be produced. In strong hydrochloric acid the substance dissolves with a dark brown colouration, and on boiling the solution, chlorine is evolved, the liquid becomes greenish yellow, and ultimately changes to the dark green colour peculiar to a solution of chromium sesquioxide in hydrochloric acid. When thrown into dilute ammonia, chromic acid is dissolved, together with all the chlorine, and a precipitate is formed possessing the properties of the chromate of chrome sesquioxide ($Cr_2O_3CrO_3$) described by Storer and Eliot. Upon this decompostion is based the method which I have employed for the estimation of the amount of chlorine contained in this body. The weighed quantity of the substance was treated with very dilute ammonia, the solution boiled for a few minutes, filtered, the precipitate well washed by hot water, an excess of nitric acid added to the filtrate, and the chlorine precipitated by the addition of silver nitrate. Two determinations of chlorine carried out in this manner on preparations made at different times gave the following results:—

Preparation I.

0·5900 grm. substance gave 0·4870 grm. silver chloride and 0·0069 grm. metallic silver.

Preparation II.

0·493 grm. substance gave 0·4250 grm. silver chloride.

Prep. I.	..	20·80 per cent Cl.
Prep. II.	..	21·32 „ „
Mean	..	21·06

* Read before the Manchester Literary and Philosophical Society, November 2, 1869.

In order to determine the amount of chromium it contains a weighed portion of the substance was repeatedly heated with strong hydrochloric acid on a water-bath until the evolution of chlorine entirely ceased; the solution was then diluted with water, heated to boiling, ammonia added in slight excess, and again boiled until the supernatant liquid appeared perfectly colourless. The precipitated chrome sesquioxide was then filtered, dried, and weighed.

Preparation I.

0·3442 grm. substance gave 0·2470 grm. chrome sesquioxide.

0·5900 grm. substance gave 0·4235 grm. chrome sesquioxide.

Preparation II.

0·5082 grm. substance gave 0·3590 grm. chrome sesquioxide.

0·5942 grm. substance gave 0·4210 grm. chrome sesquioxide.

Prep. I.	49·30	per cent	Cr.
	49·25	,,	,,
Prep. II.	48·45	,,	,,
	48·62	,,	,,
Mean	48·91		

Hence the percentage composition of the substance is as follows:—

	Found.	Ratios.	Calculated.
Chlorine	21·06	2	21·86
Chromium	48·91	3	48·54
Oxygen	30·03	6	29·60
	100·00		100·00

I have attempted to control the above empirical formula ($Cr_3O_6Cl_2$) by heating a weighed portion of the substance in hydrogen. The action of hydrogen upon the new chloride when heated is extremely energetic. At a comparatively low temperature it takes fire, combustion proceeds rapidly throughout the mass, and ultimately the substance is converted into chrome sesquioxide, hydrochloric acid, and water. Care must be taken to regulate the current of the hydrogen, since, if too rapid, particles of the finely divided sesquioxide are apt to be mechanically carried away. From an experiment, in which the gas was carefully purified from oxygen by passing it through strongly alkaline pyrogallate solution and over heated metallic copper, and then dried by transmitting it through tubes containing pumice moistened with strong sulphuric acid, the following numbers were obtained:—

0·8715 grm. substance gave 0·6150 grm. chrome sesquioxide.

Found 70·58 per cent Cr_2O_3.

$Cr_3O_6Cl_2$ gives by calculation 70·72 per cent.

I had an additional object in thus studying the action of hydrogen upon the new chloride. I considered that this action might, possibly, throw some light on the constitution of this compound. The new oxychloride may, in conformity with the analytical results, be regarded as a compound of chromous chloride with two equivalents of chromium trioxide. Now, chromous chloride, according to Moberg, may be heated in hydrogen to the softening point of glass without suffering decomposition, and if it were found that water was the only volatile product of the reaction, we should possess a certain amount of evidence for supposing that the formula $CrCl_2,2CrO_3$ represents the constitution of this substance. Experiment showed, however, that the chlorine was not so firmly united in this compound as in the chromous chloride: on gently heating the substance in hydrogen, hydrochloric acid was immediately evolved.

Péligot has described a series of salts to which are assigned the general formulæ MCl,CrO_3 and $M''Cl_2,2CrO_3$, where M represents a monovalent metal and M'' a divalent metal. The following are the names and formulæ of the salts prepared by Péligot.

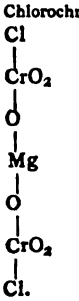
KCl,CrO_3	Potassium chlorochromate.
$NaCl,CrO_3$	Sodium chlorochromate.
NH_4Cl,CrO_3 ..	Ammonium chlorochromate.
$MgCl_2,2CrO_3$ ..	Magnesium chlorochromate.
$CaCl_2,2CrO_3$ ..	Calcium chlorochromate.

Now the new oxychloride stands in a very evident relation to these compounds. Supposing, for a moment, that the formulæ given to these substances correctly represent their constitution, then the new oxychloride may be regarded as the chromium term of the series—divalent chromium replacing magnesium or calcium.

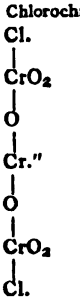
$$Cr''Cl_2,2CrO_3,$$

a formula identical with that of which I have just attempted to show the impropriety. But there is still another reason for supposing that a compound thus constituted could not exist. Chromous chloride is one of the most energetic deoxidising agents known, and we can hardly conceive it to be united in a stable compound with a substance which so readily parts with its oxygen as chromium trioxide. Hence I am disposed to regard the constitution of the salts of Péligot as very different from that implied by the above method of representation: indeed, to the best of my knowledge, the general formula assigned to these salts expresses not a single experimental fact, unless it be the mode of their decomposition by water; probably it had reference to the views of Rose and Berzelius respecting the constitution of the so-called chlorochromic acid. The following structural formulæ better represent, in my opinion, the constitution of these compounds and their relation to chromyl dichloride.

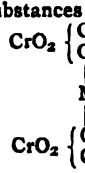
Magnesium Chlorochromate.

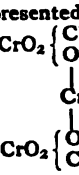


Chromium Chlorochromate.



These substances may also be thus represented—





The relation of the new oxychloride to chromyl dichloride is thus very apparent. Three molecules of chromyl dichloride when heated are resolved into one molecule of chromium chlorochromate and four atoms of chlorine.

PROCEEDINGS OF SOCIETIES.

GLASGOW PHILOSOPHICAL SOCIETY.

(Chemical Section).

The opening meeting of the session was held on Monday, the 8th instant, when Dr. Wallace, F.R.S.E., F.C.S. Vice-President, in the absence of Professor Anderson, the President of the section, delivered an address.

Dr. Wallace congratulated the members of the section upon the success which had attended their meetings during the two previous sessions, and hoped that during the present winter they would give the office-bearers of the section their cordial support in endeavouring to pro-

mote the prosecution of scientific and applied chemistry in Glasgow. The Chemical Section had been a valuable feeder to the Philosophical Society, and had been a means of encouraging the formation of other sections, as well as stimulating the enterprise of chemists in other centres of manufacturing industry. The speaker then referred to the subject of technical education, and the necessity for the establishment of chairs of technical chemistry in our universities. With regard to the munificent offer of Mr. James Young, to found a chair of technology in connection with the Andersonian University, much sympathy was felt for the eminent professor of chemistry in that institution, but they all must regret that they had not amongst them so able a man and so diligent a worker as the gentleman who had been chosen to fill the chair. It was announced, however, that Mr. Young intended to form an independent school of chemistry in Glasgow. Dr. Wallace then gave a sketch of the life and labours of the late Mr. Graham, Master of the Mint, and gave an abstract of his most recent researches on hydrogenium.

The remainder of the address was occupied with a review of the latest contributions to theoretical and applied chemistry.

The next meeting of the section will be devoted to the election of office-bearers and other business matters.

NOTICES OF BOOKS.

Chemistry: General, Medical, and Pharmaceutical, including the Chemistry of the British Pharmacopœia. By John Attfield, Ph.D. London: John Van Voorst. 1869. 8vo; 624 pages.

The object of the author in compiling this work has been to combine a lecture-companion, reading-book, and practical class-guide in one. It is specially adapted to the wants of the medical and pharmaceutical student, and, with this intention, every substance which is employed in general practice as a remedial agent is chemically described. The work opens with advice to learners regarding the method of study; in which is detailed the requirements of various examining Boards, not, as might be supposed, suggestions as to the manner in which the study of chemistry should be begun, continued, and ended—supposing any ending of such a study were ever possible.

After a short introduction, a description is given of the non-metallic elements; and we can but think that a far too brief space has been allotted to these important bodies. There is, moreover, a want of definiteness which we regret to notice; take, for example, chlorine:—

"*Source.*—This element is a gas. Its chief source is common salt, more than half of which is chlorine. *Preparation.*—About ½ of an ounce of salt, and the same amount of black oxide of manganese, are placed in a test-tube, with sufficient water to cover them. On adding a small quantity of sulphuric acid, the evolution of chlorine commences. . . . During these manipulations, the operator will have noticed that chlorine is of a light green colour. . . . The distinctive property of chlorine is its bleaching power. . . . Chlorine readily decomposes noxious gases, and hence is one of the most powerful of *deodorisers*. Used in excess, it arrests and prevents putrefaction; hence is one of the best *disinfectants*. . . . After the gases (H and Cl) have mixed, the mouths of the tubes are quickly in succession brought near a flame, when explosion occurs, and fumes of hydrochloric gas are formed."

Now, we can imagine nothing more detrimental to the student than the singular want of exactness which is exhibited here at the very outset of the work. He will very naturally imagine that chlorine is a gas under all conditions known to us; that it is readily prepared without heat; that it possesses somewhat the colour of green peas, instead of, to our eyes, a dingy yellowish green, in which the yellow predominates over the green; that its chief property is its bleaching power; that it decomposes all noxious—that is, all unwholesome, or unhealthy, or hurtful—gases; and, finally, that hydrochloric acid gas is visible. We would particularly urge Mr. Attfield to attend more to details in the next edition of his work; for a chemical treatise which lacks accuracy is of little worth, specially to the student.

The "metallic radicals" are discussed at length and with some minuteness; the principal salts are described, and synthetical and analytical reactions are given, accompanied by a symbolic representation of the changes which occur. We are glad to notice that the derivation of words is introduced as frequently as possible, and though we cannot always agree with the roots which are given, it is undeniable that even an indication of the derivation of complex words often affords much assistance to the memory of the student. We would recommend to Mr. Attfield's notice, in connection with this subject, the "Essay on Metallick Words," of Sir John Pettus; the "Lexicon Etymologicon," of Gerard Vossius; and the useful little "Etymological Dictionary," of James Donald. The account of the metallic radicals is concluded by a useful "Analytical Chart for Metals," and by certain "Analytical Memoranda."

A detail account of the "Salts of Acidulous Radicles" is next given, then "Salts of Rarer Acidulous Radicles," their analytical detection, a very concise table of the solubility or insolubility of salts in water, and a chapter on "The Analysis of Salts."

About an eighth of the work is given to the following substances:—Alkaloids, Amylaceous and Saccharine Substances, Glucosides, Alcohol and Allied Bodies, Albumenoid and Gelatigenous Substances, Pepsine, Fatty Bodies, Resinoid Substances, Colouring Matters; and the following is an example of the mode of treatment:—

"*Strychnia or Strychnine.*—Formula, $C_{21}H_{22}N_2O_2$; molecular weight, 334. *Source.*—This alkaloid exists in nux vomica (*Strychnos nux vomica*), and in St. Ignatius Bean (*Strychnos Ignatius*), chiefly in combination with lactic acid. *Process.*—According to the official process for its preparation (*strychnos*, B.P.) the nuts, disintegrated by subjection to steam, and, after drying, grinding in a coffee mill, are exhausted with spirit, the latter removed by distillation, the extract dissolved in water, colouring and acid matters precipitated by acetate of lead, the filtered liquor evaporated to a small bulk, the strychnia precipitated by ammonia, the precipitate washed, dried, and exhausted with spirit, the spirit recovered by distillation, and the residual liquor set aside to crystallise. Crystals of strychnia having formed, the mother liquor, which contains the brucia of the seeds, is poured away, and the crystals of strychnia washed with spirit (to remove any brucia) and re-crystallised." "Properties." "Reactions." "The Physiological Test," which we certainly think might be conducted in a more humane manner, although the frog is, as usual, the victim. And *àpropos* of this, we all remember how the frogs once demanded of Jupiter a king, and what they got for it; now, considering how often frogs are sacrificed on the altar of science, we do think they have a right to demand something from Jupiter in recompense therefor. If there be any believers in metempsychosis in this age, let them think how terrible would be the second death of a relative whose soul had taken up its abode in a frog selected for Mr. Attfield's "Physiological Test." "A small frog" (there is a ray of humanity in the use of the word *small*, for the size might have been left to the discretion of the experimenter) "placed in an ounce of water, to which 1-100th of a grain of a salt (acetate) of strychnia is added, is, in two or three hours, seized with tetanic spasms on the slightest touch, and dies shortly afterwards."

The chapter on "Chemical Toxicology" appears to us to be precise and accurate, but far too short (seven pages) for so important a subject. The "Examination of Morbid

Urine and Calculi" occupies eleven pages, and is accompanied by some very good plates of urinary deposits drawn by Mr. H. B. Brady, who is a careful microscopist.

The remainder of the work is devoted to "Quantitative Analysis," and occupies about one-sixth of the entire contents of the book. It is divided into the following sections:—Introductory remarks; Measurement of Temperature; Specific Gravity; Weights and Measures; Correction of the Volume of Gases for Pressure and Temperature; Volumetric Analysis; Gravimetric Analysis; Dialysis. We may specially notice a very detail table (p. 459) for the quick conversion of thermometric degrees; a long list of specific gravities of "official liquids;" and comprehensive tables of from five to seven decimal places of metrical measures and their corresponding English representatives.

Throughout the work we find at the end of each chapter a list of "Questions and Exercises," containing in all 1031 questions. These should be carefully worked out by the student, and will do much to impress facts upon his mind; it is needless to say that the only way in which they can be beneficial is if they are answered direct from memory, not after immediate reference to the book; thus a chapter should be read and if need be re-read, and a week or fortnight afterwards the questions apertaining to it should be answered.

The appendix commences with a long "Table of Official Tests for Impurities in Preparations of the British Pharmacopœia," arranged in the form of "Name of Preparation;" "Impurities;" "Test;" "Page." This will be found of the very greatest value to the pharmaceutical student, and should be so tried and tested that it is fixed in his memory. Then we have "Saturation Tables," and tables of the percentage of various acids and alkalies in solutions of various gravity, and finally a list of the apparatus and reagents required for the three months course of practical chemistry at the hospitals. We are glad to congratulate Mr. Attfield upon an unusually good index containing more than 5000 references, and extending over forty-four pages. To still further facilitate reference, three kinds of type are introduced into the index, a practice which might more often be followed with much advantage.

The work is not remarkable for any speciality of treatment or design; it bears no great stamp of originality upon it, but there is evidence of much hard work, and it is eminently comprehensive. Mr. Attfield has, however, attempted to put too much into a small space; that which is gained in variety of matter is too often lost in clearness of expression and in detail. He has laboured well at the work, and has introduced the most recent matter (such as the accounts of apomorphia and apocodeia) but what the work really wants is a careful, and by no means hurried, examination of each individual part, with a view to greater accuracy with equal conciseness; it is a grand mistake to attempt too much in books of this nature.

Now the motto and key note of the work, which is to be found over against the preface, is taken from the "De Augmentis Scientiarum" of Francis Bacon, and is to the effect that some men seek for knowledge from curiosity and inquisitiveness, love of lucre, a livelihood, or reputation, and "but few for employing the Divine gift of reason to the use and benefit of mankind." If our author will look at the original passage, he will find the above a rather loose translation of the last phrase, for it is said "Paucissimi, ut donum ratione divinitus datum in usus humani generis impendant;" and if there were any other word expressing even a less number than "paucissimi" we fear it would have to be employed. If he be among those "paucissimi" he is indeed a happy man, and we envy him. And neglecting all the other reasons for which knowledge is coveted and communicated, who can say he is not among those of whom Bacon speaks as "alii existimationis gratia?" We candidly confess we cannot. No; if this work is to have a Baconian motto at all, we venture to imagine that this will be more appropriate:—"Homo Naturæ minister et interpres tantum facit et intelligit, quantum de Naturæ ordine, re vel mente observaverit; nec amplius scit aut potest."

The Sewage Question Settled by the Purification of Water, and the Manufacture, from Town Sewage, of a Dry and Portable Manure. London, 1869.

In this pamphlet we have an account of the works of the Native Guano Company, at Leamington. If the analyses which are given are reliable, the process certainly seems of much value. The organic matter is separated from the sewage by the addition of "a *solution* of animal charcoal, blood, clay, alum, magnesia, and other chemicals;" it is then allowed to settle, and, after drying in the air, it is ready for use as a manure. The supernatant fluid is colourless, and fish have lived for months in it. The deposit is in the form of a heavy black mud, about the consistency of treacle, and scentless. The following analysis shows the composition of the solid portions of the sewage, and of the fluid which remains after the addition of the compound which precipitates the organic matter (the bulk of liquid is not mentioned):—

	Organic Matter.	Mineral Matter.	Total.
Average of 50 samples of sewage	17·2	37·4	54·6
" " " effluent water	1·4	16·9	18·3

The town of Leamington has about 20,000 inhabitants, and yields nearly 600,000 gallons of sewage daily; from this about 5 tons per day of the dried manure is procured, inclusive of 10 cwts. of ingredients added as precipitants. The dry manure, as sold, possesses the following composition:—

Water	14·1
Organic matter	22·4
Phosphate of lime	9·6
Earthy and alkaline salts	11·2
Insoluble silicates	42·7
	100·0
Nitrogen = ammonia	4·2

The cost of manufacturing the manure is £1 10s. per ton, and it sells for £3 10s. per ton; and the total amount expended on the works has been less than £4000. It is very obvious that, until the precise nature of the substances added as precipitants is made known, together with detail and repeated analyses of the sewage, and of its precipitated products, it would be very unwise to do more than call attention to the scheme, the further application of which we shall await with some interest.

MISCELLANEOUS.

Production of Oxygen Gas.—Five hundred pounds of manganate of soda furnish two and a-half cubic yards of oxygen every hour. This charge is placed in a retort, and superheated steam passed over it; in *five minutes* all the oxygen is extracted from this quantity of the salt. Hot air passed over this residue for *five more minutes* restores all the oxygen given up, and the result of an hour's continuous work, or six extractions of oxygen and six re-oxidations, is two and a-half cubic yards of oxygen. This oxygen, when it issues from the gasometers, contains about fifteen per cent of nitrogen, but, by letting the first portions escape, the quantity of this mixture can be reduced to two and a-half per cent. M. Tessie du Mothay affirms that one ton of manganate of soda will yield one hundred cubic yards of oxygen daily, or more than 36,000 per year, *and this without having to renew the salt once.* —R. J. Fowler, *in the British Journal of Photography.*

CHEMICAL NOTICES FROM FOREIGN SOURCES.

In accordance with the generally expressed wishes of our friends and readers, we have effected arrangements to enable us to give, under the above heading, notices of EVERY CHEMICAL PAPER IN THE WORLD, *as soon as possible after publication. Whenever possible, these notices will appear in the form of carefully prepared, although necessarily brief, abstracts; as respects papers either too long or too abstruse to render condensation possible, their titles will be chronicled; and in all cases accurate reference will be made to the original publication. The two half-yearly volumes of the* CHEMICAL NEWS, *with their copious indices, will therefore be equivalent to an English edition of the "Jahresberichte," with the additional advantage of keeping the readers week by week on a level with the latest advances of science.*

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, November 8, 1869.

This number opens with a—

Reply to the Last Note of M. Thenard on the Subject of the Heating of Wines.—M. Pasteur.—The purport of this paper is to refute some erroneous statements made on this subject, about which a great deal more fuss is made than is consistent with its importance.

The Changes which Flowers of Sulphur and Finely-Triturated Sulphur Undergo when Brought in Contact with Certain Soils.—M. H. Marès.—The author of this paper, a wealthy landed proprietor, and a scientific man of some standing, states the following facts:—Since the year 1854, the sulphuring of vines has become a regular practice in a portion of the south of France; on an average, there has been employed about 100 kilos. of sulphur to the hectare (2·471 acres), making, in sixteen years, 1600 kilos., although the quantity has been far larger in some districts. The question as to what becomes of all this sulphur has attracted the attention of the author, who has instituted a series of experiments and observations at Launac, near Montpellier. The main result of these researches is, that the sulphur is transformed into sulphuric acid, even during the dry summer season, in the short space of time elapsing between the beginning of July and the latter end of August. Sulphate of lime is formed, in case the soil is calcareous, as in the instance alluded to. The conversion of sulphur is more rapid in case the soil has been manured, but not a trace of sulphuretted hydrogen is then given off; or, if given off at all, it is immediately decomposed by the porous substance of the soil, and oxidised to sulphuric acid. The author found sulphate of lime even to a depth of 50 centimetres below the surface of the soil, which does not contain any of that salt but the merest trace, it being a well-known fact that Montpellier, and, indeed, the greater part of the littoral of the Mediterranean, in Southern France, is made up of a tertiary limestone formation. This mode of the disappearance of the sulphur explains the necessity of constantly repeating the sulphuring operation of the vines. The author observes that it appears that the presence of sulphate of lime is a prophylactic against the attacks of the vines by the *Phylloxera vastatrix*, since the vineyards in the Département de l'Hérault, which have been regularly sulphured, are free from the attacks of an insect which ravages at present the vineyards in the neighbouring departments of the Vaucluse and Bouches du Rhône.

Transformation of the Hydrate of Chloral into Chloroform within the Animal Body.—M. Personne.—According to M. Liebreich, the hydrate of chloral should be transformed into chloroform, when coming into contact with the alkali of the blood, according to the following formula:—

$$C_4HCl_3O_2,H_2O_2=C_2HCl_3+C_2H_2O_4;$$

that is to say, that the hydrate of chloral should become split up into chloroform and formic acid. This statement of the Berlin gentleman above named has been found incorrect by several French chemico-physiologists; and, in order to set the question at rest, the author of this memoir has instituted a series of experiments, partly with fresh blood, and partly with live animals, and has also made other crucial experiments, with the result that the hydrate of chloral is really split up—when in contact with blood in a living animal—first, into chloroform and formic acid, which, however, are ultimately converted into chloride of sodium and formiate of soda.

Chloride of Gold.—M. Debray.—The author says, It is a well-known fact that, when chloride of gold is submitted to a temperature of about 200°, it is first decomposed into protochloride of that metal and chlorine, and, if the temperature still rises, into chlorine and metallic gold. It is, however, possible to obtain crystals of chloride of gold by sublimation, by the following process:—A current of chlorine gas is made to act upon gold beaten out to a thin foil (not gold-leaf), placed in a glass or porcelain tube, and heated to 300°, at which temperature the volatilisation takes place and ruddy-coloured crystals of the chloride are obtained. The author observes that Boyle was the first who stated that chloride of gold is volatile, to some extent, without dissociation.

Bronze fit for Sonorous Instruments.—M. Riche.—It appears that, at the request of M. Dumas, in his capacity as President of the Committee for the French Mints, the author has made a series of experiments at the Hôtel de la Monnaie, Paris, on divers alloys of bronze brought from China and Japan, containing tin and copper in the proportion of 20 and 80. There have been cast, at the works just named, bars of bronze containing, respectively, 21·5, 20·0, and 18·5 per cent of tin; these bars have been submitted to hammering at temperatures varying between bright red heat and the ordinary temperature of the air. When cold, this metal is as brittle and as breakable as glass; at from 300° to 350°, a perceptible improvement takes place; and at dull red heat the metal works as easily as iron or aluminium bronze; even under the steam hammer, the metal is flattened without breaking, and may be beaten out to sheets of a millimetre thick, but requires, if hammered, a constant annealing; while, under the rolling-mill it is even better and more rapidly wrought. When hot, the metal can be cut as if it were iron or steel; with the latter metal it agrees in having a very fine grain and being very homogeneous. It can be soldered without difficulty with jewellers' solder. The density of these alloys was found to be as follows:—Bronze with 21·5 per cent of tin, after having been cast sp. gr., 8·938—after hammering, 8·929; bronze with 18·5 per cent of tin, cast sp. gr., 8·882—after hammering, 8·938; bronze with 20·0 per cent of tin, cast sp. gr., average of three estimations, 8·914—after hammering, 8·920. These alloys are very sonorous, and similar to that of the Chinese gongs.

Yellow Coralline.—M. Laudrin.—The author states that, according to his experiments, the yellow coralline is as little poisonous as the red dye of that name, also known as peonine.

Sugar Contained in Melons.—M. Petit.—The author has carefully studied the formation, as well as the disappearance, of sugar (crystallisable cane) in various fruits. As regards the melon, the rind never contains any other sugar than glucose; the pulp contains glucose in unripe state; and while the process of ripening is proceeding, cane sugar is formed, and increases in quantity, so as to be very soon in excess of the glucose. The formation of cane sugar begins in the most sour part of the fruit—that is to say, in the pulp surrounding the seeds; the formation of cane sugar is not, therefore, due to the previous existence of glucose, nor does the former result from the latter.

Polytechnisches Journal von Dingler, first number for October 1869.

This number contains the following original papers and communications relating to chemistry or allied sciences:—

Smoke-Consuming Furnace.—M. Miguet.—The consumption of smoke remains a great desideratum for industrial as well as domestic fire-places; from what is stated in this paper, to which some engravings are added, it appears that a real improvement has been made in this direction by the author, who is not, however, fully acquainted with what has been done concerning this subject in England.

Machinery for the Manufacture of Gas from the more Volatile Portions of Petroleum.—Dr. Petersen.—After referring to the advantages of gas for illuminating purposes in general, the author reviews and describes, accompanied and illustrated by engravings, some mechanism devised by German makers, for making and burning a mixture of air and vapours of what is now called gasoline; sp. gr., 0·682. The apparatus consist mainly of an air-compressing pump and reservoir for air; and for the gasoline, which, in a current of air, if not too cold, is readily and completely volatilised, and yields, on burning from an argand burner, a light equal to 18 standard candles, while the cost is only a trifle higher than good cannel-coal gas. Gasoline, as prepared on the large scale, is quite free from sulphur and ammonia, and its combustion is complete, resulting in the production of water and carbonic acid only. The apparatus, for five lights, costs 100 thalers (£15); for 200 lights, 750 thalers (£112 10s.).

Waters Contaminated with Fatty Matters considered as Feed-Water for Steam Boilers.—M. Triepike.—The author states that it has frequently been observed that new steam boilers have become quite unfit for service in consequence of getting leaky, and that this defect is due to the fact that the feed-water often becomes contaminated with dirty grease, which is forced into the boilers along with hot water, and is derived from the grease used in packing of the piston-rods and other parts of the machinery. The author states that the addition of 1 lb. of crystallised soda upon 10,000 lbs. of feed-water, is sufficient to prevent the effect ascribed to greasy matter taking place; and this confirms the observations made by MM. Börsig and Farcot, the eminent engine-builders of Berlin and Paris.

Quantity of Metallic Lead met with in Litharge.—Dr. Wittstein.—The author refers to the well-known mode of the manufacture of litharge on the large scale, and states that a colleague of his (an apothecary) had called his attention to the fact that it had often happened to him while making *emplastrum diachylon simplex*, to discover metallic lead in the vessel wherein that operation was performed The author instituted a series of experiments, which gave, as result, that, whereas some kinds of litharge are quite pure oxide, other samples contained from 1·25 to 3·10 per cent of metallic lead in finely-divided state. Pure litharge, free from metallic lead, should dissolve freely in acetic acid. If the litharge contains lead, it remains insoluble.

Bismuth from Peru.—Dr. Barth.—Since bismuth has become a rather expensive metal, more attention has been paid to the search for its ores. The author obtained a large sample of bismuth from Peru, which, on being analysed, was proved to contain, in 100 parts:—Bismuth, 93·372; antimony, with a little tin, 4·570; copper, with a trace of iron, 2·058. This bismuth is very valuable, on account of

being quite free from arsenic and sulphur, and is very suitable for pharmaceutical use.

Coal-Tar Colours.—M. Chateau.—100 lbs. of coal-tar yield—3 lbs. of raw, and 1½ lbs. of pure benzol. This quantity yields—3 lbs. of nitrobenzol, 2·25 lbs. of rosaniline, 3·37 lbs. of aniline red, and 1·12 lbs. of fuchsine; 1 lb. of pure fuchsine requires 3,000 lbs. of pit-coal. The quantity of coal-tar produced by the entire number of gas works of Europe is sufficient to yield, annually, 53,000 cwts. of fuchsine.

Analysis of an Eatable Clay.—M. Hebberling.—The author obtained, from a friend residing at Berbek, Kedirie, Java, a clay which is eaten by the natives and regularly sold in the markets. In 100 parts, this substance contains:—Silica, 39·711; peroxide of iron, 9·806; alumina, 25·939; lime, 3·025; magnesia, 1·352; protoxide of manganese, 0·591; potassa, 0·572; soda, 3·858; water and volatile matter (including 0·506 per cent of ammonia) 14·801—of this material, 72·792 per cent is insoluble in hydrochloric acid.

Les Mondes, November 11, 1869.

This number contains the following original papers and communications:—

Instructions Given by the Conseil de Salubrité (Board of Health) concerning the Use of Domestic Heating Apparatus.

Rendering Petroleum and Paraffin Oils Uninflammable and Inexplosive.—M. Garnier.—The author somewhat verbosely discusses this subject. The main facts brought forward are that experience has sufficiently taught that the temperature of minimum inflammability at 110° F. (43°) is too low, and that, very properly, that temperature should be altered to 180° F. (82°). The author next states that it is possible to render these oils uninflammable and devoid of smell by a chemical process which is not further explained, but which, while rendering the oils absolutely safe does not interfere with their proper use and applications.

Oleaginous Plants.—M. Heuzé.—Among the *accusés de réception*, attention is called to a very useful work, treating, in a practical manner, on all vegetables the seeds of which produce oil of any kind, recording the history, cultivation, diseases, and, in one word, everything relating to this subject. The book is highly eulogised as the work of a very competent authority who holds office as Inspector General of Agriculture.

Agronomic Stations and Agricultural Laboratories.—M. Grandeau.

Preservation of Beet-Root.—Count Robrinski d'Arlovetz.—One of the drawbacks of the manufacture of sugar from beet-root has always been, and is yet, the proper mode of preservation of the roots, which, in fact, is a problem not so readily solved, and least of all in countries subject to severe winters, since, if the roots are frozen, they are spoiled. The author is a large landed proprietor in Russia (where, by the bye, the manufacture of sugar from beet-root is greatly encouraged, it being the well-known policy of the Government of that empire to become, as much as possible, independent, for articles of home consumption, from other countries). The following conditions are to be complied with for properly attaining this object:—(1) No root should be at more than one metre's distance from a proper current of air; (2) every cubic metre of beet-roots requires at least a surface of 30 square decimetres, freely exposed to air; (3) that the cellars in which the roots are stored be aired every day, and care taken that the temperature therein does not rise above 4°; (lastly) care has to be taken that the roots do not become flabby by evaporation of too much water (10 to 12 per cent of their weight), in which case it would be necessary to water the roots, which, however, is always a dangerous proceeding, since it may lead to putrefaction.

Preservation of Stone by the Use of the Black Oxide of Copper and its Salts.—Dr. Robert.—This paper treats on a very interesting subject. The author proves that the decay of stone, granite, marble, limestones, sandstones—in a word, all natural building stones—is the effect of a concourse of various causes, and that among these a very minute lichen, the *Lepra antiquitatis*, is one of the worst enemies of the stone; and this to such an extent that, for instance, the beautiful marble sculptures of the well-known Parc de Versailles, will, unless proper measures are taken for staying the process of decay, be unsightly and ugly masses of dirt, and quite irretrievably lost as works of art within another fifty years. The author, taking as instances such buildings, at Paris, as the Bourbon Palace, the Palais du Corps Législatif, the Mazarin Palace (l'Institut), the Mint, and others, points out that dust, spider's-webs, and the action of rain combine with the minute lichen above alluded to, to call forth the decay of stone, especially of such parts, first, where any sculpture or ornamental carving promotes the deposition of dirt and dust. The author conclusively proves (and brings on instances which every one can see, and which, moreover, are important, in consequence of the length of time which has elapsed since the protective action of the black oxide and salts of copper commenced), that the action of the two last-named substances is, undoubtedly, preservative to stone. In reference to granite, the author states that (and an instance thereof can be seen at Waterloo Bridge) this stone is, also, according to the experience of Egyptian engineers, far more readily affected by a moist climate than one would be led to believe. The obelisk of Luxor, brought from Upper Egypt to Paris, has become blanched and full of small cracks during the forty years it has stood on the Place de la Concorde, while forty centuries had not perceptibly affected it as long as it was in Egypt. Granite, in a moist clime, becomes the seat of a microscopically-small cryptogamic plant, which greatly aids destruction; and it is, moreover, a well-known fact, that the disintegration of this stone, consisting of three separate minerals (quartz, mica, and felspar), depends very greatly upon the thorough and intimate mixture, as well as upon the chemical composition, of the same, each of these minerals, separately, being readily enough weathered.

Cultivation of Sugar-Cane in New Caledonia.—M. Joubert.—It appears, from a letter written by the person just named, that New Caledonia will become a sugar (cane) producing country. There are two sugar works in existence already, and two others are being built; the necessary machinery having been shipped from the Ile de la Réunion. Since it is a well-known fact that Cuba and other countries from which a very large proportion of the supply of sugar is obtained, are rapidly on the decline, as regards quantity, it is a gratifying fact to find that the country above named will soon be enabled to supply a not inconsiderable amount of this commodity.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 15, 1869.

From the *procès verbal* of the first meeting of this Society held after the holidays, we learn that, among other foreigners, the following Englishmen have been elected members:—Professor Crum-Brown, of Edinburgh, and Dr. W. Kellner, of Woolwich. The president, Prof. A. W. Hofmann, alluded, in a few words, to the death of the late lamented Mr. T. Graham, who was an honorary member of this Society. As a token of respect to the deceased *savant*, the assembly rose *en masse*, and a deep silence was observed for a few moments. The president next exhibited to the members a medal made of the alloy of palladium and hydrogenium, sent over by the late *savant* just alluded to, a few days before his death, to Professor Magnus, of Berlin; this medal bears on one side the effigy of Her Majesty Queen Victoria, and on the other side the name of Graham and the words "Palladium-Hydrogenium, 1869." There is added to the medal a short paper, which states that the medal contains 900 times its own bulk of hydrogenium, and, since the thickness of the medal is 1 m.m., a layer of hydrogen of a height of nearly 1 metre is condensed in that thickness of metal.

The following papers were read:—

On Chromates.—M. C. Freese.—The researches on this subject extend over a series of the salts alluded to, beginning with silver. The author distinctly points out that there exist only a neutral and a bichromate of the oxide of that metal, but no basic salt. The protoxide of mercury yields a normal neutral salt. By precipitating an excess of HgN_2O_6 with $K_2Cr_2O_7$, the precipitate obtained is not decomposed by washing with water. There exists only one basic chromate of peroxide of mercury. The older works on chemistry speak of basic chromates of copper of a green colour; the author says that green colour is due to basic sulphate of copper, or to hydrated oxide. The only known and well-defined chromate of copper, Cu_2CrO_5+2aq, is brown-coloured. Cupro-chromate of potassa is produced when cold solutions of $CuSO_4$ and K_2CrO_4 act upon each other; the double salt so obtained is split up by boiling water into K_2CrO_7 and sesquichromate of copper—

$$KrCu_3Cr_2O_{12}+2aq=(K_2Cr_2O_7)+(Cu_2CrO_5+2aq).$$

The chromates of zinc, cadmium, nickel, and cobalt are briefly alluded to, as, also, the basic chromate of protoxide of manganese.

On Sulphine Compounds.—M. Dehn.—The author says—Since it has been proved by M. Oefele that, when sulphide of ethyl acts upon iodide of ethyl, there is formed a monatomic radical, wherein the nitrogen is replaced by sulphur, I have tried to obtain similar compounds from diatomic alcohol radicals, using the sulphide of ethyl and bromide of ethylen as starting-point for my experiments. When these substances are heated in sealed tubes, along with water, to about 130°, two different series of action and products are observed; among these, triethylsulphine-platinchloride was obtained—

$$\left.\begin{matrix}C_2H_5\\C_2H_5\\C_2H_5\\Cl\end{matrix}\right\}S,PtCl_2;$$

also ethylen-diethylsulphine-platinum-chloride—

$$\left.\begin{matrix}C_2H_4\\C_2H_5\\C_2H_5\\Cl_2\end{matrix}\right\}S,2PtCl_2$$

also trimethylsulphine-bromide, C_3H_9SBr. In 100 parts—Carbon, 22·93; hydrogen, 5·75; sulphur, 20·38; bromine, 50·96. The paper enters into a lengthy discussion on the labours of MM. Cahours, Kolbe, and others on this subject.

Calculation of the Heat Emitted by the Combustion of Organic Compounds.—M. Thomsèn.

Contribution to the History of the Salicylic Compounds.—M. Henry.—This is the third portion of a memoir on this subject, subdivided into the following sections:—Nitrile of salicylic acid—

$$C_6H_4\begin{matrix}HO\\CN\end{matrix}$$

Nitrile of benzoyl-salicylic acid—

$$C_6H_4\begin{matrix}(C_7H_5O)O\\CN\end{matrix}$$

Metachlorobenzonitrile—

$$C_6H_4\begin{matrix}Cl\\CN\end{matrix}$$

Metachloronitrobenzonitrile—

$$C_6H_3(NO_2)\begin{matrix}Cl\\CN\end{matrix}$$

New and General Method for the Formation of Nitriles.—M. Henry.—The concluding portion of a long essay on this subject.

Some Sulphuretted Compounds of Isopropyl.—M. Henry.—This paper treats of:—Sulphocyanide of isopropyl, $C_3H_7.CNS$, a fluid of 0·963 sp. gr. at 20°, boiling at about 150°. Sulphur isopropyl, $(C_3H_7)_2S$, boils at 105°, and enters into combination with several metallic chlorides, the mercurial compound being a crystalline substance of the following formula:—$(C_3H_7)_2S,HgCl_2$. Mercaptanisopropyl, $(C_3H_7)HS$, boils at 45°, and acts energetically on peroxide of mercury, yielding a crystalline compound, $(C_3H_7)2HgS_2$; the alcoholic solution of this substance yields, with salts of lead, yellow-coloured precipitates, with acetate of copper a white-coloured precipitate, and the same with solutions of the salts of peroxide of mercury.

Some Derivatives of Oxybenzoic Acid.—M. Heintz.—The author describes the following substances:—A diethylether—

$$C_6H_4.OC_2H_5.COOC_2H_5,$$

a clear, colourless, oily liquid, boiling at 263°; its sp. gr., at 20°, is 1·0725; at 0°, 1·0875; its co-efficient of expansion is 0·000735. On saponification, this ether yields an acid, $C_6H_4.OC_2H_5.COOH$, a solid substance fusing at 137°; it yields salts with potassa, baryta, lime, and oxide of silver. Acetoxybenzoic acid, $C_6H_6.OOCCH_3.COOH$, a solid fusing at 127°, readily yielding salts with alkalies and the alkaline earths. Oxybenzoic-monethyl-ether, a fluid; formula—

$$C_6H_4.OH.COOC_2H_5;$$

freezes at −12°, but does not become fluid again until at 72°. (All the formulæ here quoted are exactly reproduced from the original.)

Action of Chloride of Mercury upon Sulphocarbanilide and Sulphocarbotoluide at a Higher Temperature.—M. Buff.—After referring to the experiments of MM. Merz and Weith on this subject, the author says—When a mixture of finely-powdered chloride of mercury and sulphocarbanilide is heated to about 150°, the mixture first fuses, next begins to give off a quantity of hydrochloric acid and sulphuretted hydrogen gases, and after the lapse of many hours the mass exhibited the odour of phenylsenföl (phenylated essential oil of mustard); while in the neck of the retort some crystals of hydrochlorate of aniline were found. The mass in the retort was first treated with boiling water, and next with alcohol, leaving a residue of mercury and sulphur; by this process, a basic substance, soluble in water, was obtained, which has been called tricarbohexanilide by MM. Merz and Weith, and triphenyl-guanidine by Prof. A. W. Hofmann. This substance fuses at 145°; when it is heated with sulphuric acid, sulphanilic acid is formed. The alcoholic solution yielded a solid crystalline matter, fusing at 235°, and exhibiting all the characteristics of a phenylated urea. When sulphocarbotoluidide is treated in the same manner, but at a temperature between 165° and 180°, a mass was obtained which exhibited a strong odour of oil of aniseed; the mass was at once exhausted with alcohol, yielding, after a complex process of purification, crystals of tritolylguanidine and sulphocarbotoluidide. The formation of tritolylguanidine is explained by the following formulæ:—

$$\left.\begin{matrix}CH_3-C_6H_4\\H\end{matrix}\right\}N-\underset{\underset{N}{\|}}{C}-N\left\{\begin{matrix}C_6H_4-CH_3\\H\end{matrix}\right.$$
$$C_6H_4-CH_3$$

A New Phosphamide.—M. Wichelhaus.—After referring to the labours of MM. Fittig, Gerhardt, Kekulé, and others, the author points out that, when phosphorus perchloride acts upon benzol-sulphamide, the product of that reaction need not be, as is generally supposed, benzol-sulphamide-chloride. On repeating the experiment, the author obtained, by means of a complicated set of reactions, a substance, $C_6H_5SO_2NPCl_4$; the reaction should, therefore, be represented by the following formula:—

$$C_6H_5.SO_2NH_2+PCl_5.Cl_2=Cl_2+HCl+C_6H_5.SO_2NHPCl_2.$$

The substance resulting from the benzolsulphamide appears to be a phosphamide, and is called by the author *benzolsulphurylbichlorphosphamide*—

$$\begin{matrix}NH(C_6H_5.SO_2)\\PCl_2\end{matrix}$$

Under the title of "Correspondence," M. V. von Richter writes from St. Petersburgh as follows:—The study of chemistry and the number of scientific chemists has of late years so rapidly increased in Russia that, after a general meeting of scientific men of the empire (held at the capital, in January, 1868), the Government permitted (on the 28th of October of that year) the establishment of a Chemical Society for the empire, upon the conditions that the seat of the Society should be the capital city, and that none but really scientific chemists should be elected as members. The president of the Society is elected for five years consecutively, and this office is held by M. Zinin. The meetings take place monthly, except the three summer months; at the meeting of 11-23 September last the following communications were made:—

Action of Iodine upon the Silver Compound of Succinimide Dissolved in Aceton.—M. Menschutkin. Iodine of succinimide is obtained in crystals belonging to the quadratic system; at 153°, this substance is decomposed, succinimide being again formed. Iodine does not act upon the sodium combinations of formanilide and acetanilide.

Benzimide.—M. Zinin.—The author states that, when this substance (formula, $C_{28}H_{18}N_2O_2$) is heated, along with water, in sealed tubes, it is split up into oil of bitter almonds and the amide of an acid as yet not well determined.

Nitrotoluol.—MM. Beilstein and Kuhlberg.—The authors exhibited a series of preparations of this substance; among these, solid nitrotoluol, boiling at 237°, and fluid nitrotoluol, boiling at 221°. The latter yields fluid isotoluidine.

Preparations of Thymol.—MM. Engelhardt and Latschinoff.—When thymol is acted upon by anhydrous phosphoric acid, propylen and γ cresol is formed. This latter substance differs from α and β cresol, which are obtained from two toluol-sulpho acids; but the boiling point of these three cresols is 190°. This concludes the correspondence from St. Petersburgh.

On Ethylenferrochloride.—M. J. Kachler.—When an ethereal solution of chloride of iron is heated for some hours in a sealed tube up to about 150°, a solid greyish-coloured substance is obtained. The author finds that this substance is, after having been purified, a compound $C_2H_4.Fe_2Cl_3+2H_2O$. The formation of this substance is represented by the following formula:—

$$\left.\begin{matrix}C_2H_3\\2C_2H_3\end{matrix}\right\}O+2Fe_2Cl_3=2(C_2H_4.Fe_2Cl_3)+2\left.\begin{matrix}C_2H_3\\H\end{matrix}\right\}O+2Cl.$$

This compound is not formed when the ether is perfectly anhydrous, and could not be obtained when, instead of ether, alcohol was used.

Balsam of Peru.—M. Kachler.—The author first reviews the labours of the large number of scientific men who have taken up and investigated this subject; and next describes, at very great length, his experiments, which gave, as result, that 100 parts of this balsam consist of 20 parts of benzile alcohol, 46 parts of crude cinnamic acid, and 32 parts of resin. There is appended to his paper a critical review of the labours on this same subject recently published by M. Delafontaine, from which it appears that the Peru balsam of commerce is a substance of variable composition, as has been very frequently brought forward and proved by scientific as well as pharmaceutical chemists.

Some Derivatives of Succinyl.—M. Weselsky.—The author describes:—Succinyl-phenol—

$$\left.\begin{matrix}C_4H_4O_2\\2(C_6H_5)\end{matrix}\right\}O_2,$$

is insoluble in water; soluble in ether, sulphide of carbon, and benzol; fuses at 118°; and boils and distils over, without decomposition, at 330°. Sulpho-succinate of potassa—

$$\left.\begin{matrix}C_4H_4O_2\\K_2\end{matrix}\right\}S_2,$$

is a solid substance, readily soluble in water, alcohol, and ether, and readily decomposed by acids, sulphuretted hydrogen being evolved. Sulpho-succinic acid, $C_4H_4O_2S$, also called sulpho-succinyl, is very soluble in water, alcohol, and ether, and exhibits a strongly acid reaction; with solutions of salts of copper, it is immediately decomposed, sulphide of copper being formed.

On Biniodide of Phenol.—MM. Hlasiwetz and Weselsky.—In the introduction to this paper, the authors review the history of some isomeric monoiodine phenols, and other compounds of phenol and iodine. Pure biniodide of phenol is a crystalline substance, readily soluble in alcohol, ether, and sulphide of carbon; fusing at 150°; subliming at a higher temperature; formula, $2C_6H_4I_2O+2H_2O$.

Products of the Oxidation of Toluol-Sulpho Acid by means of Fusing Caustic Potassa.—M. Barth.—This paper, and the next (by the same author)—

Constitution of Phloretinic Acid and Tyrosine—Are not well suited for abstraction.

On Sulphoxybenzoic Acid.—M. Senhofer.—By a lengthy process, too long for quotation, the author obtained sulphoxybenzoic acid in pure state. It is a crystalline bright green-coloured substance, $C_7H_7SO_6$, not precipitated by neutral acetate of lead, and yielding, with chloride of iron, a wine-red colour; at 160°, it loses water; the acid fuses at 208°. This acid forms compounds with lead and cadmium; the latter is an acid salt. Formula, $2(C_7H_5SO_6)Cd$. The acid does not readily form salts with alkalies.

New Mode of Formation of Protocatechuic Acid.—M. Malin—The author finds that, when sulphanisic acid is heated with fusing caustic potassa in excess, care being taken to regulate the temperature properly, and to avoid a too long continued action of the potassa, the result is the formation of protocatechuic acid; when the action is too long continued, hydrochinon is, however, formed. The acid obtained was found, on elementary analysis, to yield—C, 54·7; H, 4·0. Dried at 100°, this substance lost 10·5 per cent of water. The quantity of protocatechuic acid obtained from 16·6 grms. of sulphanisic acid amounts to about 2 grms.

Pettenkofer's Method for the Determination of Carbonic Acid.—Dr. Gottlieb.—The author states that, while, with the method alluded to, the accuracy thereof mainly depends on the care taken in the preparation of the turmeric paper used in this process (which is not described, but understood to be generally known), he has found that, when proper precautions are taken, the pigment of litmus answers the purpose as well. For this purpose, the litmus is exhausted with alcohol at 85 per cent, until it only assumes a very slight violet tinge. The alcohol is removed by evaporation on a water-bath, leaving behind a deep violet-coloured amorphous mass, the largest part of which is soluble in cold water, yielding a solution which, on the addition of an acid, assumes the well-known red colour, known as *rouge pelure d'oignon*, while alkalies do not affect it. The remainder of the litmus (insoluble in alcohol) is treated with water, yielding a blue pig-

ment insoluble in alcohol; this aqueous solution is, after removal, by filtration, of the substances of the litmus insoluble in water (impurities), at first, violet-blue coloured; but this tinge changes, on the addition of more water, into a pure blue, which, by the addition of acids, soon becomes beautifully red (*pelure d'oignon*), which tinge, however, does not become apparent unless a larger quantity of acid has been added. The author, therefore, adds to a portion of the blue-coloured fluid guttatim, some very dilute hydrochloric acid, until the fluid has assumed a wine-red tinge. When this point has been reached, the rest of the blue (original) liquid is added; and in this manner a fluid is obtained which answers the purpose of working, according to Pettenkofer's method, better than turmeric paper or tincture, since the author states that, on instituting comparative tests and assays, he found it easy to estimate to within 0·0007 grm. of carbonic acid.

NOTES AND QUERIES.

Bisulphite of Lime.—How is the "bisulphite of lime solution" which is now largely sold, possessing as high a gravity as 1·072, practically made?—A. N. Palmer.

Shoddy.—Can any of the subscribers of your valuable journal inform me the best means of reducing shoddy by acid, for mixing with phosphatic material as a manure.—Child.

Preventing Moisture in Glass Cases.—(Reply to "S. E. P.")—Use quick-lime, which absorbs both moisture and carbonic acid, and put in the case a piece of camphor wrapped in muslin, and you will not be troubled with moisture.

Standard Verification.—(Reply to "S. E. P.")—We believe that a polite application to the Astronomer Royal would obtain you what you desire; there is no doubt that at the Observatory they have the means as well as the goodwill to give every assistance for such objects.

Bleaching Syrups.—(Reply to "Andrew Van Bibber").—You can hardly expect to attain your object at all, since the colour of these syrups is due, in the first place, to caramel, and also to peculiar impurities, from which the sugar is only liberated by a process of washing with a very concentrated, and quite colourless, syrup made on purpose from best refined sugar. Filtration through charcoal (animal) will decolour these green syrups, as they are technically called, to a limited extent, and then only after having been somewhat diluted with hot water, and the filtration taking place in a room where the temperature should not be less than 80° F. By means of very finely divided pipe-clay, added previous to filtration, you may obtain a greater degree of decolouration, but it is impossible to bleach, as you call it, these syrups entirely, and since you have to dilute with water before filtration, you would have to evaporate that water afterwards, and unless that were done in a vacuum pan, your previous operations would be of little avail.—X.

Detection of Prussian Blue in Black Ink.—Prussian blue is either neutral or basic. Neither of these are soluble in water; for, although it is stated that the basic blue is soluble therein, this is incorrect, since the apparent solubility is due to an excess of the ferrocyanide of potassium. There is no means of dissolving Prussian-blue but by the use of acids, which would altogether destroy, and be incompatible with, black ink as usually made, since these acids are just those which are used to obliterate the stains of black ink. Prussian blue is decomposed by alkalies; but these would also destroy ordinary black ink. It is not very likely that ink should be tinged blue by Prussian-blue; it is probably coloured blue by a few drops of indigo carmine. As to the detection of logwood in ink, it should be borne in mind that almost all black inks are partly made with logwood, and that a tolerably good black ink is made of logwood decoction and neutral chromate of potassa. The detection of logwood is based upon the reactions of hæmatoxyline and hæmateine, but the details thereof are too lengthy to be here quoted, and can be found in works on organic chemistry.

Terra Alba.—In further reply to "Selenite," it depends upon what purpose he intends or wishes to apply it—which variety is to be preferred. Chemically, they are all the same, except that the commoner kinds contain more or less foreign matter, such as oxide of iron, &c. The best kind is carefully picked out and ground into what is technically termed "terra alba," and by some people "pearl white;" this portion is so white that it looks like good loaf-sugar. The more coloured varieties, or parts of the vein (*i.e.*, the pieces rejected as unfit for terra alba), are ground up separately, and are technically called gypsum. These kinds need no drying; but when either kind is baked, so as to lose its water of crystallisation, it becomes the setting plaster, known as plaster of Paris, used by plasterers. Terra alba (*i.e.*, the natural product) is sold very much cheaper than the artificial one made under Jullien's patent. French artificial sulphate of lime is made like Jullien's, by precipitation, I think, by Prof. Kuhlmann, but it is no better than native terra alba, or Jullien's pearl-hardening. As the artificial article would, if over-dried, lose parts of its water of crystallisation, it is never thoroughly dried. It is almost impossible to enumerate the many uses to which gypsum (a term which includes the whole) is applied; it is, however, largely used for manure, as an absorbent of ammonia, by colour makers, paper makers, and several other trades. Large quantities of the commoner kinds are made in Carlisle and that neighbourhood, and quantities of the stone are shipped, from the Seine, to Leith and other places, where it is ground, but the French stone is not good enough to make terra alba. If "Selenite" sends me his address, I will send him a pamphlet on the subject, containing the largest amount of information he can get about it, and which would be too much to be given through your columns. Jullien's patent is an English one.—Nemo.

MEETINGS FOR THE WEEK.

Monday, 22nd.—Medical, 8.
—— London Institution, 4.
Wednesday, 24th.—Society of Arts, 8.
—— Geological, 8.
Thursday, 25th.—London Institution, 7.30.
—— Royal, 8.30.
—— Zoological, 8.30.
Friday, 26th.—Quekett Club, 8.

TO CORRESPONDENTS.

R. Tatlock.—Communication received with thanks.

D. W. L.—Bloxam's "Laboratory Teaching," published by Churchill, will answer your purpose best.

J. B.—(1) A good cement for sulphide of carbon prisms is isinglass dissolved in weak spirit. (2) Heat and good ventilation will remove the smell of wood-tar from a room.

Professor Tennant, F.G.S., will deliver a Course of Lectures on MINERALOGY applied to GEOLOGY and the ARTS, at King's College, London, on Wednesday and Friday mornings, at nine o'clock, during October, November, and December, commencing October 8th. Fee, £2 2s.

A Course of Lectures on MINERALOGY and GEOLOGY will also be delivered, on Thursday evenings, at eight o'clock. These begin October 14th, and will be continued to Easter, 1870. Fee, £1 11s. 6d. Professor Tennant gives Private Instruction in Mineralogy and Geology, Illustrated by a large number of Specimens, at his Residence, 149, Strand, W.C.

PRACTICAL CHEMISTRY.
Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give Instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from Ten to Five o'clock: on Saturday from Ten till One o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses apply to Mr. Henry Matthews, the Laboratory, 60, Gower-street, Bedford Square, W.C.

Instruction in Practical Chemistry for Students resident in the South of London.

Dr. JOHN MUTER, M.A.,

Continues to receive Pupils at his Laboratory, whom he instructs in all branches of Practical Chemistry on moderate terms.

Medical and Pharmaceutical Students successfully prepared for their Examinations in a short Course of Evening Lessons. Special Instruction also in the Microscopical and Chemical Examination of Articles of Food and Drink.

Every kind of Analysis Carefully and Promptly Executed. Analyses for the Profession at Half Fees.

New Kennington Institute, 289, Kennington Road.

Instruction in Practical Chemistry and Evening Classes for the Study of Chemistry, Botany, Materia Medica, &c.

TO PHARMACEUTICAL AND OTHER STUDENTS.

Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c., wishes to inform his old Pupils and others that he continues to devote his whole attention to Education.

The Session 1869—1870 will commence on the 4th of October, when Mr. BRAITHWAITE'S Laboratory, which has been enlarged, will be re-opened at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL and TOXICOLOGICAL CLASS meets as usual every Monday and Thursday Evening, at 8 p.m., commencing October 4th.

The LATIN CLASS for the reading of the Pharmacopœia, Physicians' Prescriptions, &c., every Tuesday and Friday Evening, at 8 p.m., commencing October 5th.

The BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday Evening, at 8 p.m. The usual EXCURSIONS for the STUDY of PRACTICAL BOTANY will be continued every Saturday until further notice.

Fee to either of the above Classes Half-a-Guinea per Month; to the Botanical Excursions only, Half-a-Guinea per Eight Lessons. Pupils can enter at any period.

Gentlemen privately prepared for the Examinations of the Pharmaceutical Society, &c., the "Special Examination for Chemists in Business," and for the "Modified Examination for Assistants."

All Fees must be payable in advance.

Letters of inquiry should be accompanied with a stamped envelope Address, 54, Kentish Town Road, N.W.

Mr. Braithwaite receives a few Pupils to board in his house.

THE CHEMICAL NEWS.

VOL. XX. No. 522.

THE LATE ECLIPSE, AND ITS OBSERVATIONS IN THE UNITED STATES.

As might be expected from the easy accessibility of the entire line of totality, this eclipse has been most thoroughly observed by numerous parties, the report of whose work will in due time be presented to the scientific world. Among the methods of observation, photography played an important part, and we have now before us an admirable series of views obtained by a large party organised and conducted by Dr. Henry Morton, Professor of Chemistry in the University of Pennsylvania, whose communications have sometimes appeared in our columns.

These pictures show, in the first place, very fine definition in the telescope employed, as the roughness or mountainous character of the moon's edge is clearly given in the pictures of partial phase, as well as the sun-spots and surrounding faculæ.

Thus, Professor A. M. Mayer, who took charge of one of the three sections of Professor Morton's party, has shown, by measurement on the photographs, a change of shape in one of the larger spots during the eclipse, amounting to a motion of 2000 miles in its edges.

During totality, no less than thirteen negatives were secured, showing a large number of prominences, some massive and others delicate, as well as radiant brushes of a softer light, such as have been before seen, but never as yet photographed. By another of the sections of this large party, beside similar pictures to the above, one was obtained showing the curious phenomena known as Baily's beads.

The time of exposure determined by Professor Mayer for the partial-phase pictures was the 1-500th of a second. Those taken during totality were exposed from five to sixteen seconds.

The *Journal of the Franklin Institute* for September has sixteen pages devoted to Professor Morton's report of his expedition to Professor J. H. C. Coffin, U.S., N. Supt. of the *Nautical Almanack*, under whose authority this and other expeditions were organised, with an admirable photograph from one of the totality negatives, and several woodcuts.

One of these, showing the general character of the prominences, we here give.

The line A B represents the direction of a parallel of declination; C D a declination circle. F E is the moon's path from first contact at F. The prominences are here all shown at once; although, of course, those on the sun's eastern limb alone were seen at first, those on the west side only at the end of the totality.

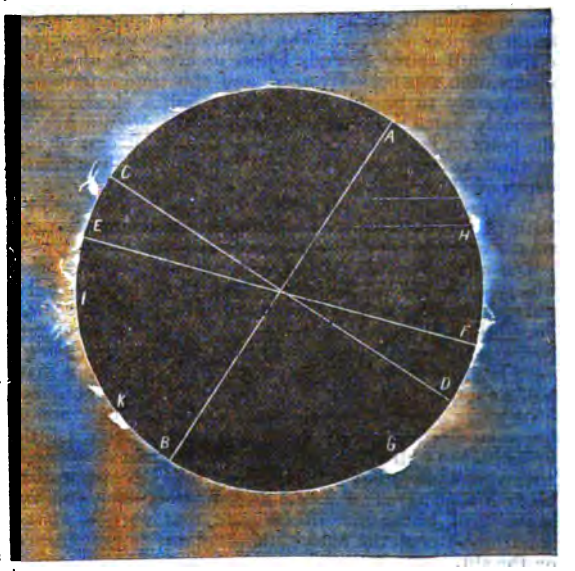
In the October number of the same journal, of which advanced sheets have been sent us, thirty-eight pages are devoted to the reports to Dr. Morton of those in charge of the various departments. From these we extract some of the most interesting portions as follows.

PHOTOGRAPHS OF THE CHROMOSPHERE.

Dr. B. A. Gould writes:—An examination of the beautiful photographs made at Burlington and Ottumwa by the sections of your party in charge of Professors Mayer and Himes, and a comparison of them with my sketches of the corona, have led me to the conviction that the radiance around the moon in the pictures made during totality is not the corona at all, but is actually the image of what Lockyer has called the chromosphere.

This interesting fact is indicated by many different considerations. The directions of maximum radiance do not coincide with those of the great beams of the corona; they remained constant, while the latter were variable. There is a diameter approximately corresponding to the solar axis, near the extremities of which the radiance upon the photographs is a minimum, whereas the coronal beams in these directions were especially marked during a great part of the total obscuration. The coronal beams stood in no apparent relation to the protuberances, whereas the aureole, seen upon the photographs, is most marked in their immediate vicinity; indeed, the great protuberance, at 230° to 245°, seems to have formed a southern limit to the radiance on the western side, while a sharp northern limit is seen on all the photographs at about 350°, the intermediate arc being thickly studded with protuberances which the moon displayed at the close of totality. The exquisite masses of flocculent light on the following limb are upon the two sides of that curious prominence at 93°, which at first resembled an ear of corn, as you have said, but which, in the later pictures, after it had been more occulted, and its southern branch thus rendered more conspicuous, was like a pair of antelope horns, to which some observers compare it. Whatever of this aureole is shown upon the photographs was occulted or displayed by the lunar motion, precisely as the protuberances were. The variations in the form of the corona, on the other hand, did not seem to be dependent in any degree upon the moon's motion.

The singular and elegant structural indications in the special aggregations of light on the eastern side may be of high value in guiding to a farther knowledge of the chromosphere. They are manifest in all the photographs by your parties which I have seen, but are especially marked in those of shortest exposure, such as the first one at Ottumwa. In some of the later views, they may



be detected on the other side of the sun, though less distinct; but the very irregular and jagged outline of the chromosphere, as described by Janssen and Lockyer, is exhibited in perfection.

This happy result is clearly attributable to the relative shortness of the time of exposure, by which the highly photographic rays of the chromosphere have depicted themselves, without obliteration by the mass of coronal light which veiled them from the eye. Let us hope that, at the next total eclipse, some impressions may be taken with an exposure not exceeding a single second. The inference seems warrantable, that, in this way, better than in any other, the internal structure of the protuberances

may be exhibited, though other phenomena may fail to record themselves.

You will observe that some of the brighter, petal-like, flocculi of light have produced apparent indentations in the moon's limb at their base, like those at the bases of the protuberances. These indentations are evidently due to specular reflection from the moon's surface, as I stated to the American Association at Salem, last month. Had any doubt existed in my mind, previously, it would have been removed by an inspection of the photographs.

Abstract of Professor Young's Report.

The observer was a member of the party under the direction of Professor J. H. C. Coffin, of the *Nautical Almanac* Office, stationed at Burlington, Iowa.

The instrument employed was a spectroscope with 5 prisms of 45° each, having faces 2¼ by 3¼ inches; the collimator and telescope had apertures of 2¼ inches, with a focal length of 17. These were connected with a "comet seeker" of 4 in. aperture and 30 in. focus, used with an eye-piece, and giving an image of the sun, 2¼ inches in diameter, on the slit of the spectroscope. A graduated screen at the slit determined positions of points on the sun's limb, and a wire micrometer measured the positions of spectrum lines. The whole was mounted equatorially with slow motion screws.

Protuberances were noted before the eclipse at + 85° to 100°, large and not very bright; at + 146°, small and bright. The photographs show another at 155°, which escaped notice; also at −70° to 80° low, but pretty bright; and at −130°, very large and bright, the principal one. Angles are reckoned on the sun's limb from the North point, + towards the East, − towards the West.

The first contact was observed by watching the gradual shortening and final extinction of the *bright line*, C, in the spectrum of the prominence, which happened to be at the point of contact. The moon's approach was perceived full thirty seconds before its actual appulse; the observation was perfectly easy, and the time determined is certainly to be relied on within half a second, and probably much less. The presence of a prominence at the point of contact is not essential to the success of the method, as there is everywhere on the sun's limb sufficient depth of chromosphere to answer the purpose.

It is proposed to apply the spectroscope to observations both of the external and internal contacts at the next transit of Venus.

During the totality, the following nine bright lines were observed in the spectrum, viz., C, dazzling in brilliance; 1017·5 (near D, the numbers refer to Kirchhoff's scale,) very bright, but not equal to C; 1250±20, very faint, position only estimated; 1350±20, like the preceding; 1474 (a little below E,) conspicuous, but not more than half as bright as 1017·5; F, next to C in brightness; 2602±2, a little fainter than 1474, position determined by micrometrical reference to the next; 2796. a little below G, the well-known Hγ line in brightness between 1017·5 and 1474; and finally *h*, or Hδ, somewhat brighter than 1474. *b* was not seen, it is supposed, on account of a mistake in carrying that portion of the spectrum through the field while there was no prominence on the slit.

*The line 1474 was recognised as belonging to the *spectrum of corona*, in the first place, by its extending clear across the spectrum, while 1017 did not, and then by its remaining visible when the slit was moved away from the protuberance, while the other lines (C and 1017) disappeared. The impression of the observer is that faint lines 1250 and 1350 behaved in the same manner, but his recollection as to this point is not very certain.

These three lines, 1250, 1350, and 1474, coincide far within the probable errors of observation with three lines observed by Prof. Winlock in the spectrum of the Aurora Borealis. The first two are not accurately enough determined, in position, to allow much stress to be put upon any apparent coincidences on their part, but the last is perfectly well known, and its exact agreement throughout with one of the fainter lines of the Aurora, when combined with the general appearance of the Corona and other considerations, give a good deal of probability to the conjecture that *our Aurora Borealis and the Solar Corona are identical phenomena*.

The line 1474 is given by both Kirchhoff and Angström (not by Huggins, who, however, omits many faint lines,) as belonging to the *iron* spectrum, and this suggests the inquiry whether we are to admit the existence of *iron* in the auroral heights of our atmosphere, or are to account for this line in the iron spectrum by some unknown substance of gaseous nature.

The corona showed, also, a faint continuous spectrum without *any trace of dark lines*. The light of this faint spectrum, tested by a tourmaline held in the hand next the eye, was strongly polarised in a plane passing through the sun's centre. As the direction of the spectroscope slit was nearly radial, it is not impossible that Prof. Pickering may be right in explaining this polarisation as caused by the successive refractions through the prisms.

Professor Young's Determination of First Contact.

In our notice of this subject we omitted to state that Prof. Young finds that the presence of a prominence at the point of first contact, though facilitating the process is not essential to his method, since the spectrum of the chromosphere is quite enough for the same purpose.

The Corona and its Photographs.

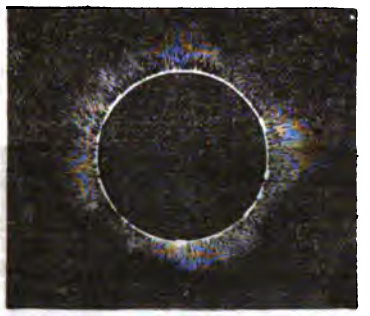
It is a very fortunate thing that the numerous parties by whom photographs were made of the late eclipse, in hardly any two instances followed the same plan of arrangement or aimed at the same class of results. Thus, the Philadelphia Expedition, in pursuance of Professor Coffin's suggestions, made their preparations with the view of obtaining such "accurate and well-defined pictures as might be the basis of astronomical calculations." In this they have unquestionably succeeded beyond all others, as we hear from all sides, now that pictures have been distributed and compared. Their views of lunar mountains, sun-spots, faculæ, chromosphere, and crepuscule being unapproached, and their views of the solar prominences only rivalled by one obtained by Dr. Curtis.

The party under Prof. Pierce, consisting, photographically, of Mr. Whipple, of Boston, (who, with Mr. Black and the late Prof. Bond, of Cambridge, made, in 1850, the first celestial photograph), addressed themselves exclusively to the recording of that strange phenomenon, the corona. To secure any impression from this object, which, notwithstanding its apparent brightness is remarkably deficient in photographic power, it was necessary to make a very small image, and to give a very long exposure.

The telescope was therefore arranged to produce an image in its principal focus simply, and during the totality an exposure of 40 seconds was given. By this means a picture was obtained, of which the accompanying cut is a very careful copy. From the long exposure and motion of the moon, as also, probably, of the light in the corona, there is little sharpness of definition,

* A careful examination of the photographs of the prominences on the eastern limb of the sun, upon which the slit of the spectroscope was directed during the first half of totality, somewhat diminishes my confidence in the conclusion of the text, as to the nature of these three lines. I think it absolutely certain that they do not belong to the spectrum of the *brilliant portion* of the prominences; but the photograph shows, in addition, an extensive nebulosity surrounding the nuclei, with a pretty definite boundary of its own. This nebulosity is best seen in No. 2 of the totality pictures taken at Burlington. Now, it is *possible* that these lines may belong to this *nebulosity*, and not to the *corona proper*; for I cannot recall, with certainty, whether the 1474 line retained its brilliance at any considerable distance from the prominences. My impression is that it did, and that the text is correct, but do not wish to be too positive. The eclipse of December, 1870, will decide, of course.

and the prominences only appear as bright spots. The general shape of the corona is, however, very well given, and the curious appearance of curvature, in some



parts, is very manifest. This and other pictures—if others than the one we have seen were made—may throw some light upon this extraordinary object.

ON RAISING A HIGHER TEMPERATURE IN CERTAIN SOLUTIONS BY STEAM OF 212° Fahr. (100° C.).

By PETER SPENCE, F.C.S.

Some twelve to fifteen years ago, the author had occasion to require large masses of liquor to be raised to a temperature of 228° F. (108·8° C.), for the purpose of extracting, by means of long-continued digestion at that heat, of alumina, in the form of sulphate of alumina, from minerals containing that earth. As time was an element of importance in his calculations, the author's aim was to heat the liquors as rapidly as possible; but lead vessels only could be used with the acid liquors; and, as it was requisite to have an iron outside vessel next the fire, the heating was a tedious operation. To overcome this loss of time, the author fitted up a digesting vessel, so as to raise the heat rapidly to 212° F. (100° C.), by injecting steam from a steam boiler into the mass of liquor; and as soon as he had obtained that temperature, he stopped off the steam, and allowed the external fire to operate alone, so as to raise the additional 16° F. (8·8° C.) required, and to maintain the temperature at 228° F. (108·8° C.), his impression being that, above 212° F. (100° C.), the steam, if kept on, would act as a cooling agent, and prevent the temperature rising. The combined operation was perfectly successful, and went on for some time, acting, as the author supposed, in accordance with his pre-conceived theory; but some circumstances led him, subsequently, to doubt whether it was so. He found that if, inadvertently, both steam and fire were left acting after the higher temperature was obtained, the temperature continued, notwithstanding. Again, when the fire was in a condition, through neglect, in which it was obviously of no use, the author was still astonished to find that, as the apparent result of the steam alone, the temperature was at a satisfactory point. This last observation led the author to test the matter in the laboratory in the following manner:—Being convinced that the high boiling point of his liquors had something to do with the phenomenon, he selected a solution of a salt (nitrate of soda) having a high boiling point—about 250° F. (121·1° C.). The nitrate of soda was placed in a vessel surrounded by a jacket; steam was let into the intervening space, until a temperature of nearly 212° F. (100° C.) was obtained; the steam was then shut off, and an open pipe immersed in the solution, and steam from the same source was thrown directly into the liquor; in a few seconds, the thermometer slowly, but steadily moved, and minute after minute progressed, until it touched 250° F. (121·1° C.). This thoroughly explained the results obtained in the digesting vessel, and became to the author of immense practical value. He discarded the use of fire applied to his vessels, which had not only been tedious and troublesome in operation, but involved a loss of many hundreds of pounds per annum in destruction of apparatus, and used only steam as a vehicle of heat. As a corroboration of the theory, which seems to explain the apparent paradox, the author finds that the temperatures of his solutions are in the exact ratios of their specific gravities, and have no connection with the temperature of the steam, which never exceeds 212° F. (100° C.). The greater the specific gravity of his acid solutions, the higher the boiling-point; and, therefore, whatever the boiling point of the solution in water of any salt, to that point, or nearly, will steam of 212° F. (100° C.) raise it.

ON MICROSCOPICAL MANIPULATION.*

By W. T. SUFFOLK, F.R.M.S.

(Continued from p. 245.)

Next in importance to the possession of a good instrument, is the having a good supply of light and knowing how to make proper use of it. The sources of light available for the microscopist's use have already been described; the ways of utilising the light so obtained, and the instrumental appliances for directing it, form the subject of this chapter.

The natural division of illuminators is into two classes—those which act above the stage of the microscope, and send light down upon an object; and those which are placed below the stage, and send light through it.

Of instruments of the first class, one—the *condensing lens*—is usually supplied with every microscope, however plainly equipped. This lens enables light to be concentrated upon the object on the stage; either a double-convex or a plano-convex lens may be used for this purpose. If the first is employed, no particular attention is required beyond placing it at such a distance above, and on one side of the stage, that the light falls at a suitable angle, and that the object is in or near the focus: should a plano-convex lens be used, its position is of some importance, as, if it is turned the wrong way, its spherical aberration is greatly increased, and, of course, a corresponding amount of light lost. The plano-convex lens, or bull's-eye, when used to concentrate parallel rays—daylight, for instance—or divergent rays, such as those proceeding from a lamp, should always be placed with its convex side turned towards the source of light, as the spherical aberration is then much less than it would be when placed in the contrary direction; if the lens is to be used for rendering parallel the divergent rays of a lamp, then the bull's-eye is to be placed in the opposite position, with its flat side turned to the lamp, and at a distance from the flame equal to its focal length. Parallel rays are required when using some of the illuminating apparatus presently to be described.

Very much may be done with the condensing lens, if skilfully used; especial care is required that it

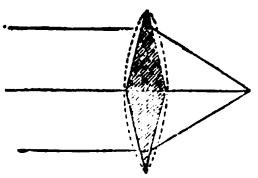
* The substance of a course of lectures delivered to the members of the Quekett Microscopical Club, January—April, 1869.

causes the light to fall on the object in the right direction, as the appearance of the surface of many substances is very different when illuminated from opposite sides; the student should, therefore, never be contented with a single observation of a strange substance, but should change its position, so that it may be viewed with the light falling upon it in as many directions as possible. This is most easily effected by causing the object to rotate while the light is directed upon it, so that the alteration caused by every change of position can be easily noted. The necessary movement is now very generally fitted, even to the stages of small instruments, and persons about to procure a microscope would do well to incur the small extra cost of this useful addition.

The light obtained by the condensing lens may be greatly augmented by using two, one of larger dimensions than the other, the light being brought to a certain degree of convergence by the first and larger lens, and afterwards concentrated by passing through the smaller one, which should be so placed as to intercept the cone of light from the large lens at the place where it is of its own diameter.

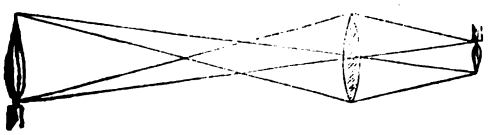
Most of the other illuminators of this class act by reflection, mirrors of various forms being employed. The optical properties of concave mirrors resemble, in many points, those of convex lenses; they cause parallel rays to converge (Fig. 19), render divergent

Fig. 19.



rays parallel, or convergent, and also form images (Fig. 20). Microscopes and telescopes can be con-

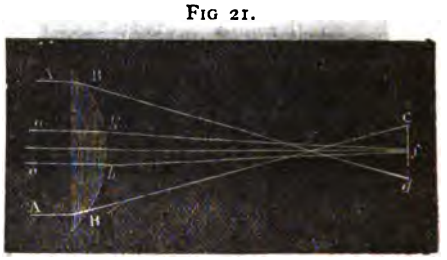
Fig. 20.



structed with mirrors or specula, instead of object-glasses; this principle is still in use as regards telescopes of large dimensions, as the difficulties of making object-glasses of large diameter are very great; the largest yet accomplished is only 25 inches, while the largest speculum (that of the late Lord Rosse) is 6 feet in diameter.

Professor Amici constructed a very efficient compound microscope, having an elliptical speculum in place of an object-glass; the plan, however, was abandoned on the introduction of the achromatic principle, although its performances were very superior to those of the non-achromatic instrument.* Concave mirrors, when formed of segments of spheres, are liable to spherical aberration, just as lenses are (Fig. 21); therefore, when it is required to render divergent rays parallel, or bring parallel rays to a focus, it is necessary that the figure of the mirror should be that of a parabola. Specula of this form are used in astronomical telescopes, the reflectors of lighthouses on the catoptric principle, and in some instruments presently to be described. The parabolic curve differs from the circle principally in being flatter at the edges and deeper at the centre. Reflecting instruments are entirely free

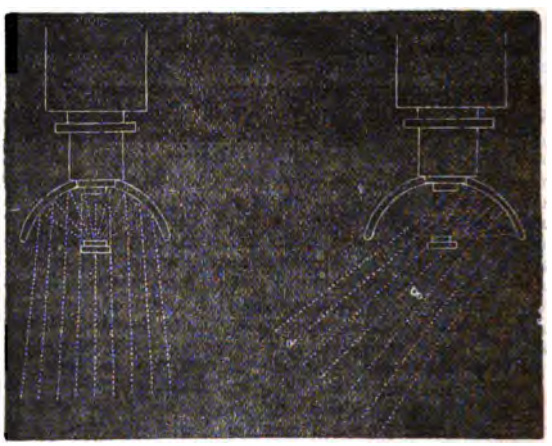
Fig 21.



from chromatic aberration. The oldest of the reflecting illuminators is that known, from the name of its inventor, as the *Lieberkuhn* (Fig. 22); it consists

Fig. 22.

A B



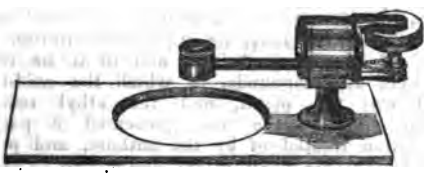
of a spherical silver mirror, perforated, to allow it to slide over the setting of the object-glass, and is so adjusted that the focus of the speculum is coincident with the working distance of the object-glass. The object is illuminated by light reflected through the hole in the stage by means of the mirror; this is again reflected, but in a very convergent state, upon the object, which will be intensely illuminated if the speculum is well adjusted to focus and properly supplied with light.

It is necessary to place beneath the object a black stop of sufficient size to fill the field of the object glass, otherwise the light from beneath entering the microscope will cause a disagreeable amount of fog and indistinctness. The best kind of background consists of a dark well or little cup of proper size painted black inside, and placed below the object; a patch of black paper or paint will, however, answer the purpose. Beck's disc holder (Fig. 23) is particularly useful for objects to be examined by the aid of the lieberkuhn, as it forms its own black stop. Its late talented inventor was very expert in the employment of this kind of illumination. The defects of the lieberkuhn are that its light is nearly vertical, and therefore, like the tropical mid-day

* One of these instruments has recently been presented to the Royal Microspocical Society; there are also several old and curious microscopes in the Society's collection.

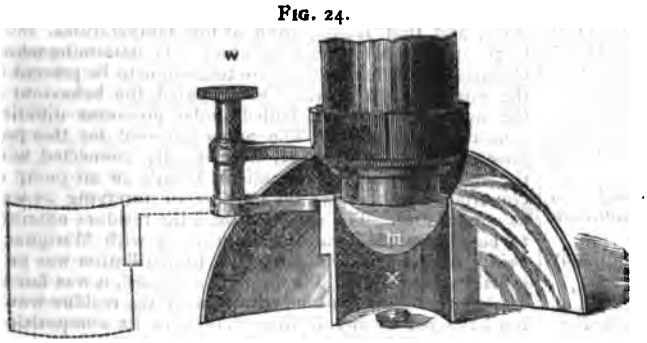
sun, casts little or no shadow; this, however, may be remedied, to some extent, by turning the mirror aside and using the light from only one-half of the speculum (Fig. 22, B); also it requires the object and its mounting to be small enough to allow the free passage of the light around it from the mirror.

FIG. 23.



These defects caused the lieberkuhn to fall somewhat into disuse; the introduction of the binocular microscope, however, caused it again to be employed, as it was found very suitable for the peculiar class of opaque objects which are so well displayed in relief by its stereoscopic power. It has, however, again been nearly superseded by an improved form, which has all its advantages besides some peculiar to itself. This improved instrument, which is known as the *parabolic lieberkuhn* (Fig. 24), is another of the

FIG. 24.



numerous contrivances of the late Richard Beck, and was described by him in the *Microscopical Quarterly Journal* for 1865 (vol. xiii., p. 116). It consists of a portion of a silvered paraboloid, which is attached by a ring to the setting of the object-glass, so that it has some range of adjustment like the ordinary lieberkuhn, but instead of the light being directed upon it from below through the hole in the stage, it is supplied from one side, which allows this form of lieberkuhn to be used with objects mounted in the ordinary way. It is necessary when lamp light is used that the rays should be rendered parallel by placing a condensing lens between the lamp and the reflector, as before-mentioned. As there is a very large reflecting surface, and from the parabolic figure of the mirror no spherical aberration, the amount of light concentrated upon the object is much greater than could be obtained from the ordinary spherical lieberkuhn. It has also the advantage of reflecting rays from one side only and of considerable obliquity. These properties make it the most perfect illuminator yet produced for viewing opaque objects by reflected light. Its effect is almost like that of brilliant sunshine, lighting up the interior of every cavity, and yet, at the same time, casting strong shadows and defining minute portions of structure in a manner hitherto unapproached. The paraboloid as usually constructed is adapted for use with objectives of from 2 inches to ⅛ focus. A very ingenious mounting, allowing a very large range of adjustment to be given to the paraboloid, has been contrived by Mr. Crouch, who uses a short adapter screwed into the body of the microscope as a support to the reflector and its fittings, which consists of sliding tubes and ball-and-socket joints, by means of which it can be placed in extremely varied positions, and is adapted for use with any microscope or object-glass fitted with the universal screw. It must be borne in mind that these advantages are gained at the expense of removing the object-glass a small distance, viz., the length of the adapter from the Wenham prism, while, to obtain the best possible definition, the back lens of the objective cannot approach the prism too closely; therefore in making choice between the two forms of mounting the paraboloid, the student must consider whether convenience with a trifling loss of definition will suit him, or whether the most perfect definition is required with the trifling inconvenience attending the ordinary form.

An addition to the parabolic lieberkuhn, consisting of a small plane mirror (Fig. 24, *m*) inclined at an angle of 45°, which is so fitted that it can be brought into the proper position for reflecting light vertically upon the object, by means of the milled head, w, has been made by Messrs. Beck, at the suggestion of Mr. Sorby, who required this contrivance for viewing the polished surfaces of specimens of iron and steel. When light is directed obliquely upon a highly polished surface, it is reflected at an angle equal to the angle of incidence, none of it enters the microscope, and the surface appears intensely black, but when illuminated vertically, all its structural peculiarities are at once brought into view. For such researches the plane speculum is indispensable, and its adaptation in no way interferes with the ordinary use of the paraboloid.

The late Richard Beck made a small paraboloid, adapted for use with the 4-10th objective. This the author had an opportunity of working with, and, although only in experimental condition, was much pleased with its performance. It was returned after trial, but has not at present been produced for sale by Messrs. Beck, probably on account of its value not being generally known. From its very short focus, it requires much more careful fitting to the objective it is intended to be used with than the larger paraboloid; but when carefully executed, it works quite as well with its own object-glass as the one above mentioned with the lower powers. The author, however, possesses one which was made for him by Mr. Bailey, of 162, Fenchurch Street, which performs admirably, and is executed in this optician's usual careful manner. The parabolic lieberkuhn is of great value with ½ inch and 4-10th objectives, as these glasses allow but little space between the front glass and the object for illumination with the condensing lens.

A very efficient illuminator was, until recently, much in use; it is known as the *side reflector*, and consists of an oblong silvered mirror of spherical figure. It has ball-and-socket and sliding adjustments, and is attached either to the stand of the microscope or else is mounted upon an independent support; it is placed on one side of the instrument,

and the light directed upon it from the opposite side. The speculum is then adjusted until the object is properly illuminated. It has, however, been superseded by the parabolic lieberkuhn before described.

(To be continued).

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, November 18th, 1869.

Dr. A. W. Williamson, F.R.S., &c., President, in the Chair.

The minutes of the previous meeting having been read and confirmed, the following certificates were read:—

For the first time—Samuel Jefferson, Secretary to the Yorkshire Board of Education, Woodville Terrace, Woodhouse Lane, Leeds; Clements Higgins, Demonstrator of Chemistry, King's College, London; James John Bourey, Analytical Chemist, 10, Stepney Causeway, E.

For the second time—Matthew H. Cochrane, 108, Paul Terrace, Glasgow; Edward Smith, Practical and Pharmaceutical Chemist, Strand, Torquay; Thomas Walton, M.R.C.S., and L.S.A., Lecturer on Chemistry at the Hull and East Riding School of Medicine, Kingston-upon-Hull; G. Manley Hopwood, 22, Grosvenor Square, All Saints, Manchester; John Wiggin, Pharmaceutical and Analytical Chemist, Ipswich; Thomas Gibb, A.R.S.M., Engineer; George Harrison, Analytical Chemist, 26, Havelock Square, Sheffield; Sir Roderick Impey Murchison, Bart., F.R.S., Belgrave Square.

For the third time—E. S. Blackwell, Analytical and Consulting Chemist, 6, St. Sacrament Street, Montreal, Canada.

The last-named gentleman was ballotted for and duly elected.

At the request of the President, a paper by William Dittmar, F.R.S.E., and George Cranston, "*On the Formation of Carbonic Ether*," was read by the Secretary.

The authors referred to Ettling's researches upon the action of sodium or potassium on oxalate of ethyl, and had endeavoured to discover the *rationale* of that action. They found that, when ready-formed sodium ethylate (ENaO) is brought into contact with oxalate of ethyl, the former compound, like the metal itself, causes the formation of carbonic ether and carbonic oxide. Dry ethylate (ENaO) was prepared by evaporating the liquid alcoholate in a current of dry hydrogen in a retort heated in an oil-bath, when the compound remained as a white porous mass. On treating dry ethylate with about eight times its weight of oxalic ether, it dissolves, and a yellowish syrup is formed, which sometimes gelatinises on standing. If this mixture is gradually heated, at about 80° C. large quantities of gas (chiefly carbonic oxide) are evolved, and the mass darkens till it is almost black. At 140° the reaction ceases. The mass is then distilled at a temperature not exceeding 200°; and the distillate consists of carbonate of ethyl, sometimes mixed with undecomposed oxalate, and always contaminated with ethylic alcohol. The black residue dissolves in water, and contains oxalate and formiate of soda, and also the soda salts of some complex organic acids. Experiments in order to obtain a basis for the speculation on the nature of the reaction led to the following conclusions:—"ENaO" parts of ethylate, acting upon an excess of oxalic ether, decompose 4 "$(EO)_2C_2O_2$" parts of oxalate of ethyl, and produce 3 "$(EO)_2CO$" parts of carbonate of ethyl, 3 "CO" parts of carbonic oxide, and about 0·4 "EHO" parts of alcohol. The behaviour of dry ethylate of potassium on oxalate of ethyl was qualitatively analogous to that of sodium ethylate; the reaction is, however, more energetic, and begins at a lower temperature.

The President said they were indebted to the authors for their interesting communication. It was remarkable that those bodies should effect the same decomposition as had been observed with the metals themselves; and he hoped the authors would follow up the reactions, so as to show the phases of which they consisted.

Professor Wanklyn said that he had read a paper to the Society in 1864, on "The Constitution of the Ethers of the Fatty Acids," and in it he regarded the ethers as compounds, in which the acid-forming radical was the metal, and the ethyl oxide the chlorous radical. He also presented a paper on the reaction treated of by the authors, and predicted that ethylate of sodium would decompose oxalic ether, and produce carbonic oxide and a carbonic ether, and that an unlimited quantity of oxalic ether might be decomposed by a given quantity of ethylate of sodium; but the paper was not published by the Society. It was gratifying to him to find his prediction verified so long afterwards by gentlemen who had made the experiment without any communication with, and quite independently of, himself.

"*On the Dissociation of Liquid Sulphuric Acid*," by W. Dittmar, F.R.S.E., was then read.

In the opinion of the author, the experiments of Marignac on this subject seemed to show that "H_2SO_4" exists as a definite chemical individual only in the solid state, and that H_2SO_4, even at low temperatures, must be regarded as a molecular mixture. To determine which chemical individuals they were to assume to be present in the mixture, Mr. Dittmar investigated the behaviour of the acid H_2SO_4 when boiled under pressures differing from the atmosphere. The apparatus used for this purpose consisted of a retort, hermetically connected with the receiver, which communicated with an air-pump so constructed as to serve the purpose of rarefying as well as condensing. The results proved the residues obtained to be almost identical in composition with Marignac's acid. As the acid first subjected to distillation was only a little stronger than the product obtained, it was fair to assume that a further concentration of the residue would not have led to any further change in its composition. Sulphuric acid, when boiled down under any pressure between 3 c.m. and 314 c.m., behaves almost like a mixture of the stable hydrate $12SO_3 13H_2O$ + excess of SO_3, but the existence of a stable *molecule* of this composition could not be deduced from this fact. The observed facts could be accounted for without denying that in liquid sulphuric acid, even at its boiling point, the majority of the molecules have the composition H_2SO_4. It was known that 'H_2SO_4' vapour consists chiefly of isolated molecules of SO_3 and H_2O; and it was in accordance with Clausius's theory to assume that in liquid sulphuric acid, even at low temperatures, a number of the molecules have assumed the state of motion corresponding to a temperature beyond that of dissociation. The higher the temperature, the greater the ratio of the number of the dissociated molecules to that of the unchanged ones. The liberated H_2O's and SO_3's being formed in the midst of a mass of (H_2SO_4)'s will, probably, mostly unite with comparatively cold molecules of H_2SO_4, and form compounds $H_2SO_4 + H_2O$ and $H_2SO_4 + SO_3$ respectively; supposing the latter compound to be less stable than the former, it is easily understood that, in the distillation of sulphuric acid, the higher the temperature, the more SO_3 will predominate in the vapour.

Professor A. H. Church, M.A., then read a communication on "*Namaqualite*." This mineral occurs in Namaqualand, South Africa, in thin layers of silky fibres, which are true crystals. It is of a pale blue colour; its density is 2·49. Isolated crystals appear transparent under the microscope. In the closed tube it gives off much water, when heated becoming black. The mean per-

centages deduced from the analysis of five specimens are as follows:—

H_2O	32·38
CuO	44·74
Al_2O_3	15·29
CaO	2·01
MgO	3·42
SiO_2	2·25
	100·09

Regarding the silica as an intruding substance, and the lime and magnesia as replacing a small part of the cupric oxide, the author thought the mineral might reasonably be considered as a compound of 4 molecules of cupric hydrate, 1 molecule of aluminium hydrate, and 4 molecules of water. The oxygen ratio between the protoxides, the aluminium oxide, and the water, is 4:3:11 nearly, and corresponds to such a view. The mineral belongs to the rare class of hydrous oxides, in which a protoxide and sesquioxide are united. The fact that it is crystallised, as well as definite and constant in composition, demands for it specific rank.

"*Chemical Researches on New and Rare Cornish Minerals (No. 6)—Hisingerite,*" by Prof. CHURCH, M.A. Under this name the author provisionally describes a brown amorphous mineral found in Cornwall. Its chief characteristics are as follows:—Amorphous; reniform; fissured; dark brown; streak, pale; rust, brown (in some specimens, olive-brown); Fragile; fracture, irregular conchoidal; hardness, 2·75; density, 1·74. Before blowpipe in closed tube much water, having faint permanent acid reaction. On charcoal, decrepitates and becomes black. Fuses with difficulty in outer flame to a red brown bead. Boiled in acids leaves a siliceous skeleton.

The mean percentages deduced from three analyses run thus:—

Fe_2O_3	52·94
SiO_2	36·14
H_2O	10·49
	99·57

The mineral also contained 0·82 per cent of P_2O_5 and traces of magnesia.

"*On Chloranil and Bromanil*" (No. II.*), by Dr. STENHOUSE, LL.D., F.R.S., &c.

When phenol was acted upon by chloride of iodine in the presence of water, it yielded a brown crystalline mass, from which chloranil was obtained. Red oil, obtained in the ordinary process for preparing chloranil, dissolved in a dilute boiling solution of caustic soda, a sufficient quantity of potassic chlorate, and hydrochloric acid, yielded small crystalline scales, consisting of chloranil and terchlorquinone. When the red oil was digested with nitric acid, sp. gr. 1·36, red fumes took place. Chloropicrin distilled over; chloranil remaining in the retort.

Chloranilic Acid was prepared as follows:—Five parts of chloranil, moistened with alcohol, were added to a cold solution of 6 parts of potassic hydrate in 150 of water; the mixture occasionally stirred till the yellow scales disappeared and part of the potassium salt had crystallised out in dark red needles. The chloranilic salt is precipitated by adding from 10 to 15 parts of chloride of sodium; it is then washed with a solution of common salt, and purified by one or two solutions in boiling water, precipitations by common salt, and a final crystallisation from distilled water. The chloranilate is then dissolved in 100 parts of boiling water, and 10 parts of hydrochloric acid is added; on cooling, the chloranilic acid is deposited.

The alkaline chloranilates are prepared by neutralising pure chloranilic acid with the corresponding alkaline hydrate or carbonate.

Chloranilic ether, $C_6Cl_2(C_2H_5)_2O_4$.—One part of chloranilate of silver is digested with five of ethylic iodide until the silver salt is converted into iodide, the excess of iodide of ethyl distilled off, and the chloranilic ether extracted by boiling alcohol.

The action of chloride of iodine on chloranilic acid gave large transparent plates, which were found to be oxalic acid, and a heavy oily layer, which the author is at present investigating. The author is also investigating the action of bromine on chloranilic acid; he has already obtained a substance corresponding closely to $C_6Br_8Cl_3HO$.

Bromanil.—To prepare this substance, Dr. Stenhouse places bromine in a flask with one-third of its weight of iodine and five times its weight of cold water. On adding phenol through a long digestion tube, a strong reaction takes place; the phenol adhering to the side of the tube is then washed down with five parts more boiling water, and the whole digested for one or two hours at 100° C. When cold, the semi-solid contents are freed from the mother liquor with a Bunsen's vacuum filter, and digested with bisulphide of carbon to remove terbromophenic acid. Tolerably pure bromanil remains.

When bromanil was digested with hydriodic acid and phosphorus, bromhydranil, $C_6Br_4O_2H_2$, was obtained. The author also procured terbromhydroquinone and terbromquinone from the action of sulphurous acid on bromanil.

Bromanilic acid was prepared in a similar manner to chloranilic acid.

Bromanil phenylamid was prepared by adding an excess of aniline to bromanil dissolved in benzol, and washing the almost black crystalline plates with boiling alcohol.

The author concludes with an account of the action of bromine on bromanilic acid.

The PRESIDENT, in thanking Dr. Stenhouse for his interesting communication, referred to the beautiful specimens of some of the compounds described which had been sent to the Society by Dr. Stenhouse.

"*On the Salts of Acetylinated Ethyl,*" by J. ALFRED WANKLYN.

The liquids having the empirical formulæ $C_6H_{10}O_3$, $C_8H_{14}O_3$, and $C_{10}H_{18}O_3$, respectively, and which were discovered by Geuther, and Frankland and Duppa in the course of their researches on acetic ether, and to which a variety of names have been assigned by their discoverers, have been found to be, in reality, the salts of the new organic radical, "acetylinated ethyl." They show two characteristic reactions—With ethylate of sodium they yield salts of common ethyl, the acetyl being exchanged for hydrogen, thus:—

Butyrate of acetylinated ethyl.

$$\overbrace{\left.\begin{matrix}C_2H_4(C_2H_3O)\\C_4H_7O\end{matrix}\right\}O}+\left\{\begin{matrix}C_2H_4Na\\H\end{matrix}\right\}O=\left\{\begin{matrix}C_2H_5\\C_4H_7O\end{matrix}\right\}O+$$
$$+\left\{\begin{matrix}C_2H_4Na\\C_2H_3O\end{matrix}\right\}O$$

With baryta water, they give alcohol, a ketone, and carbonate of baryta—

$$\left.\begin{matrix}C_2H_4(C_2H_3O)\\C_4H_7O\end{matrix}\right\}O+\left\{\begin{matrix}Ba\\H_2\end{matrix}\right\}O_2=\left\{\begin{matrix}C_2H_4H\\H\end{matrix}\right\}O+$$
$$+\left\{\begin{matrix}C_2H_3O\\C_3H_7\end{matrix}\right\}+\left\{\begin{matrix}Ba\\CO\end{matrix}\right\}O_2,$$

wherein H_2 replaces acetyl and butyryl, and the latter do not form acetate and butyrate of baryta, but a ketone and carbonate of baryta, being an example of the common method of producing ketones, but at the temperature of the water-bath instead of at a low red-heat.

The Society then adjourned till Thursday, December 2nd.

We have received the following letter from Professor Wanklyn, respecting his researches on the subject of Messrs. Dittmar and Cranston's memoir:—

* For the author's first paper on this subject, see CHEMICAL NEWS, vol. xvii., p. 129.

To the Editor of the Chemical News.

Sir,—The paper suppressed by the Chemical Society in the year 1864, to which reference was made in the course of the discussion of Mr. Dittmar's admirable research "On the Production of Carbonic Ether," was a short note on that subject, and was intended to form an appendix to my paper "On the Constitution of the Ethers." In this note, I expressed the belief that the production of carbonic ether was due to the action of ethylate of sodium on oxalic ether, and that the reaction would be found to belong to the class of so-called catalytic actions. These predictions were made avowedly in virtue of the general views of the structure of the ethers which were then entertained by me, and were, in my opinion, useful as tests of the validity of those theories, and also as illustrative of their nature and meaning. The authorities of the Society, however, appear to have entertained a different opinion, and, out of a tender regard for my reputation as a chemist, suppressed the note.

On referring to the report in the Chemical News (vol. x., p. 233), I find the following passage at the end of the abstract of my paper on the ethers:—"An explanation of the formation of carbonic ether from oxalic ether was also given." The note itself has, I believe, never been published, but was referred to by me in a paper "On Formic Ether" (see Chemical News, vol. xvii., p. 144).

At that period, I was unprepared for such an exercise of paternal solicitude on the part of the officers of the Society, and took no steps to avoid suppression. In more recent times, I have always been in readiness to resist dictation of this sort, and, though frequent attempts have been made on the part of the Society to suppress papers either of my own or of my former colleagues, have never submitted to the smallest suppression. The practical result has been that which might have been anticipated, viz., the scattering of my papers through different journals; and, if chemists should hereafter complain that what I have written on a given chemical subject is not all of it to be found in the pages of the *Chemical Society's Journal*, but is diffused through the scientific press, the fault lies with the officials of the Society, and not with me.—I am, &c.,

J. Alfred Wanklyn,
Corresponding Member of the Royal Bavarian Academy of Sciences.

London, Nov. 20th, 1869.

GLASGOW PHILOSOPHICAL SOCIETY.

(Chemical Section).

A meeting was held on Monday evening, the 22nd inst., Dr. Wallace, F.R.S.E., Vice-President, in the chair.

The following four gentlemen were elected Members of Council, in room of four who retired by rotation:—James Anderson, Esq., 98, St. Vincent Street; Dr. John Clark, Anderson's University Laboratory; James Couper, Esq., St. Rollox Chemical Works; P. M. Moir, Esq.

Dr. Wallace then made some remarks on the results of his examinations of some waters taken from cisterns in the vicinity of water-closets, in various parts of Glasgow. He stated that the results of his observations, which were made conjointly with Dr. Anderson, went to show that there was not a trace of any gas present which could arise from the decomposition of animal matter. A microscopic examination did not show the presence of any insoluble matters other than ordinary dust.

A new and very different source of danger, however, was revealed by the analyses. It was found that water which had got warm by remaining in pipes which were exposed to warmth, either by proximity to the usual hot-water pipes or otherwise, was frequently contaminated with lead to such an extent as to render the use of the water for dietetic purposes positively dangerous.

NOTICES OF BOOKS.

Outlines of Chemistry, or Brief Notes of Chemical Facts. By William Odling, M.B., F.R.S., Fullerian Professor of Chemistry at the Royal Institution. London: Longmans, Green, and Co. 1870. 8vo.; 468 pp.

This work consists of detail notes of the lectures which Dr. Odling has been in the habit of giving at St. Bartholomew's Hospital during the last seven years; of such notes, in fact, as are now frequently printed separately and distributed among an audience. It is much to be wished that this plan (which, if we remember rightly, was first introduced at the Royal Institution in 1862) was more often followed, as it must perforce give the listener a clearer idea of the lecture than he could otherwise have, while it prevents his attention from being diverted by the writing of notes. A lecture, after all, is chiefly for puposes of demonstration, and experiments are too often lost by the student who is desirous of making full notes; it is, moreover, always essential that numbers and complex formulæ should appear in other forms than as a momentary utterance or on the black-board. This book is virtually a collection of lecture-notes; and the main object of the author was "to furnish the students of St. Bartholomew's with an abstract" of his lectures. Of necessity, such a collection of notes must form "*outlines* of chemistry;" it is as a picture with all the broad details of design introduced, but without the filling-in and finishing. It is not intended to be used by itself, "but as a companion to the teachings of the lecture-room, and as an aid to the appreciation of more complete works, such as Miller's "Elements" and Watts's "Dictionary."

The work is divided into twelve chapters, the first whereof, although introductory, plunges into the middle of things, and treats of the law of volumes, equivalency, heat of combination, and so forth, and of some of the more complex questions of classification. Thus, in the section on "Acids and Salts," we find such paragraphs as the following:—"Mono-, tri-, and penta- equivalency of same perissad element as nitrogen, in different compounds as N'_2O, H_3N''', and $ClH_4\overset{v}{N}$? Di-, tetra-, and hexa- equivalency of same artiad element as sulphur, in Cl_2S'', $Cl_2S''''O$, and $S''''O_2$, and $Cl_2\overset{vi}{S}O_2$, and $\overset{vi}{S}O_3$? Persistency of different equivalent values in double decomposition, as of stannous and stannic salts by lime—

$$Cl_2Sn'' + CaO = Cl_2Ca + Sn''O$$
$$Cl_4Sn'''' + 2CaO = 2Cl_2Ca + Sn''''O_2$$

Theoretical views concerning change of equivalency, real or apparent. Hypo- and hyper- saturated compounds, saturation by one another of two equivalencies of same atom (?)." Useful sections on the "Formula of Water," and on "The Heat of Combination," are found at the end of this chapter.

The second chapter treats of hydrogen and of the halogen elements, and the third of the oxygen elements. In the latter, the sulphur acids are discussed at some length, and the various actions of sulphuric acid on metals, oxides, and salts are illustrated very concisely by five reactions, in which, by the interchange of hydrogen for metal, we have sulphurous acid liberated when the strong acid acts upon metals; hydrogen when the weak acid acts upon more basylous metals; water or sulphydric acid when the acid acts upon oxides or sulphides; water and oxygen when it acts upon peroxides; and acids when it decomposes salts. This sort of classification of the action of one substance upon others of varied composition is of great use in fixing the separate qualities of a chemical substance in the mind of the student. In each case, we have one constant and two variants, but each variant is the type of a class, and thus the changes become grouped within comparatively narrow limits. The system of types and of analogies is carried out to the fullest extent;

on every possible occasion, related substances are compared; such we have in the list of the "oxides of hydrochloric acid, sulphuretted hydrogen, and phosphine" (p. 65). These expressions will appear strange to some of us, but Dr. Odling does not bind himself to any one name; thus H_3PO_4 is both an oxide of phosphine and ortho-phosphoric acid; $HClO_4$ is an oxide of hydrochloric acid and perchloric acid. In the above comparison, they are obviously called oxides of hydrochloric acid, sulphuretted hydrogen, and phosphine, because the compounds are similarly oxygenated, the HCl, H_2S, and H_3P being found in each compound of its respective series.

Chapter 5 treats of the carbon elements, and extends over nearly a hundred pages. To this group belong carbon, silicon, tin, and lead, a grouping which is founded on the tetrad character of these elements, as indicated by their combination with hydrogen, ethyl, fluorine, and chlorine. In the account of silicon, the terms *Siliconides* and *Siliconetted hydrogen* are employed. It is certainly surprising how such a word as "siliciuretted hydrogen" came to be introduced into chemistry, but it was undoubtedly made in agreement with such words as carburetted, sulphuretted, phosphuretted, &c. Nearly the whole of this chapter is devoted to carbon and monocarbon compounds. These are divided into three groups; viz., the methylic typified by H_4C, the formic typified by formic aldehyde, H_2CO'', and the cyanic typified by hydrocyanic acid, HCN'''.

Chapter 6 gives a description of the Sodium Elements—sodium, lithium, silver, potassium, rubidium, cæsium. With these monad metals are considered the triad metals, thallium and gold, "on account of their each forming a series of monad compounds corresponding to those of potassium and silver." The group of magnesium elements consists of calcium, strontium, barium, beryllium, magnesium, zinc, cadmium, and mercury; and these are distinguished by replacing the hydrogen of hydrochloric acid in the proportion of one atom of the metal to two atoms of hydrogen.

The remaining chapters treat of the other groups of metals; to wit, the Tin Elements—aluminium, tin, didymium, thorium, and indium; the Arsenic Elements—titanium, zirconium, cerium, yttrium, erbium, lanthanum, arsenic, antimony, bismuth, vanadium, niobium, and tantalum; the Chromium Elements—chromium, molybdenum, and tungsten; the Iron Elements—manganese, iron, cobalt, nickel, copper, and uranium; and the Platinum Metals—palladium, platinum, rhodium, iridium, ruthenium, and osmium.

One of the most prominent features of this work, as of all Dr. Odling's works, is the constant attempt to classify—to collect together compounds which, however much they may differ in some respects, have at least one cardinal and prominent resemblance; and, in such classifications, he has wisely exercised his judgment in deciding which kind of resemblance shall determine the grouping of diverse bodies. This must ever be a matter of difference of opinion among chemists, although, for the good of the science, it is much to be wished that an universal mode of classification should obtain throughout the chemical world. The section on *Equivalency* in the first chapter treats specially of the modes of classification; the primary hydrides into mono-, di-, tri-, and tetra-hydrides; and so with chlorides, &c. Then the division of the elements into monads, diads, triads, and tetrads, and into artiads and perissads.

The derivation and explanation of terms, and the arguments in favour of the applicability of some in preference to others, is left to more detail works on chemistry; as, also, is any account of manipulation, and of the preparation of the various simple and compound substances described. This is by no means an elementary work. It is best fitted for the teacher and for advanced pupils; to those who are engaged in the delivery of long courses of lectures it will be invaluable. It is eminently methodical and systematic; if chemistry could ever be what Dr. Whewell calls "a classificatory science," Dr. Odling would be the man to make it so. The very nature of this work makes it *staccato* in character; and, since we have gone to music for a word, we may also say it is entirely free from *appogiature*. There is not a word too much; every sentence is sharp, precise, and to the point; it is a *précis* rather than a finished treatise. It reminds us of a map in which the principal cities and towns are introduced, while the villages are omitted. Compared with a detail "handbook" or "cours de chimie," it is as M. Logerot's "Souvenir du Nouveau Paris" compared with Fielding's map of that city.

Dr. Odling does not employ one form of phraseology; he appears, indeed, rather to prefer to vary the names of a substance as much as possible. He uses such names as cupric nitrate and zinc chloride "indifferently and alternatively" with nitrate of copper and chloride of zinc. The fact is, we are not to say of chemical compounds "by their names shall ye know them;" we must be so familiar with their nature and composition that we shall know them under any reasonable designation whatsoever. It is thus with friends; at first the name is the entity; while, on better acquaintance, the individuality of the entity manifests itself, and we know him and remember him for his character and qualities, the name in its first form of significance having of necessity vanished. It is thus, also, we suspect, that Dr. Odling wishes us to treat chemical compounds. Thus viewed, such terms as "oxide of hydrochloric acid," "nitro-marsh-gas," and "hydro-sodium-carbonate," grate less upon the ear than would otherwise be the case: it is familiarity with the compound designated which is to level the barrier of names. If our friend A. B. chooses to change his name to X. Y., he is the same to us, but to a possible future friend, Z., he virtually becomes another being, because Z. knew him not before the change. Similarly, if we are familiar with the composition of the body HCN''', we may call it, "indifferently and alternatively," prussic acid, or hydrocyanic acid, or nitro-marsh-gas, or cyanic hydride; but, to the neophyte, the matter will appear in a very different light. "What's in a name?" Ask the gentleman who whilom bore the name of *Cimex Lectularius*, or that other one (whose name we also prefer to Latinise) who recently wrote to the *Times* complaining of the adverse influence of his name upon his daughter's matrimonial prospects; and no wonder, for he was called *Johannes Curtacola*. Modern chemistry does not allow her children to have fancies of this sort. In all seriousness, our science does contain a marvellous medley of names, derived from the most varied sources—Hebrew, Greek, Latin, Arabic, Spanish, Old High German, and Low Latin, combine to mystify and perplex the student.

Let us now justify our remarks as to the general character and the extreme conciseness of this work by giving one or two extracts taken at random.

"Methene, H_4C, obtainable from methyl alcohol, H_4CO, through intervention of methyl chloride, iodide, &c., by action thereupon of nascent hydrogen; from formic acid, H_2CO_2, by its transmission over ignited baryta; and from disulphide of carbon, CS_2, the sulpho-derivative of carbanhydride, by its joint reaction with sulphuretted hydrogen upon ignited metallic copper."

Again, in the account of the hydrocyanic and cyanic ethers, we find concise, comprehensive statements of the following nature:—

"β-cyanide of methyl unknown. β-cyanide of ethyl made by reaction of cyanide of silver and iodide of ethyl in sealed tubes—$IH_5C_2 + AgCN = AgI + H_5C_2CN$; also by action of chloroform on ethylamine, in presence of potash—$HCl_3C + H_2(H_5C_2)N = 3HCl + H_5C_2.CN$. Resistance of this cyanide to action of alkalies. Its immediate decomposition, with absorption of water, under the influence of acids, into formic acid and ethylamine—

$$H_5C_2.CN + 2H_2O = H_2CO_2 + H_2(H_5C_2)N.$$

Throughout, Dr. Odling has employed names which indicate the relationship of bodies to each other rather than

their absolute composition. "For example," he says, "although I have no doubt whatever that corrosive sublimate is really a dichloride of mercury, there was a time when I was equally certain of its being a monochloride; and, taught by this experience, I now prefer to distinguish it by the name 'mercuric chloride,' and calomel by the name 'mercurous chloride;' whereby I merely imply, what never has been a matter of question, that the ratio of chlorine to mercury is greater in the one compound than in the other." As a consequence of this method, it happens that bodies differently constituted have similarly constructed names; thus CuO, Fe_2O_3, and SnO_2, are cupric, ferric, and stannic oxides respectively. Dr. Odling has carefully avoided the use of any method of graphic notation: "It has," he remarks, "I believe, exerted, and still continues to exert, a most prejudicial influence on the study of chemical science, by making the fanciful sticking together of variously-pronged discs of more importance than the investigation of phenomena." Again, he has not expressed reactions molecularly, because, as he candidly remarks, "In the majority of reactions, I do not myself know what the molecular formulæ of the reagents and products concerned are, and do not think it worth while to make a pretence of knowing."

Now, we have been wont to regard Dr. Odling as the extremest radical in the world of chemists—indeed, as a sort of revolutionary red republican; and we rejoice to find him taking an intermediate course, leaving extreme views to the Raspails and Rocheforts of our science. There is no denying the fact that the science has progressed so rapidly of late that the prominent attitude of chemical thought is generalisation; facts have accumulated in such an astounding manner as the army of workers has increased that the desire of collecting particulars has, in many cases, been replaced by the desire of generalising upon the knowledge already attained. The temptation is, indeed, strong, but the science is not yet ripe for such a process. Certain chemists, seeing a little light in the distance, are hallooing before they are out of the wood. They may spare their voices yet awhile, and had better seek for the path which shall lead others from the gloom hereafter. We pray them to bear in mind Plato's exquisite parable of the dim cave, full of shadows which come and go; and to remember that there are two ways of investigating and discovering truth, to the first of which many have attached themselves. "*Altera a sensu et particularibus advolat ad axiomata maxime generalia atque ex iis principiis eorumque immota veritate judicat et invenit axiomata media. . . Altera a sensu et particularibus excitat axiomata*, ascendendo continenter et gradatim, *ut ultimo loco perveniatur ad maxime generalia; quæ via vera est, sed*" (too often, we fear) "*intentata.*" With a great din of shouting sounding in his ears, Dr. Odling has wisely preferred to reserve his own voice until he is fairly and fully clear of the wood, and we shall gladly trust ourselves to his guidance.

MISCELLANEOUS.

Obituary.—We regret to have to record the death of Dr. Frederick Penny, the Professor of Chemistry in the Andersonian Institution, to which chair he was elected in July, 1839. His published papers and researches, as well as his great success as a teacher of chemistry in Glasgow, testify to his ability as a chemist and physicist; and his loss will be felt by a numerous circle of students and friends.

Operatic Fireworks.—The manner in which scientific discoveries are applied to utilitarian or, at least, to money-making purposes in this material age is well illustrated in a stage effect obtained in the performance of "Faust" at the Grand Opera in Paris. The scene represents *Mephistopheles* in the act of tapping a great wine-vat, whereupon the stream flows like liquid fire, and, falling into the wine-tub, bursts into flame. Usually, the wine stream has been represented by a "squib," but, in the present instance, by very different means. A vessel for containing water was furnished at one side with a horizontal ajutage, and at the other, immediately opposite the ajutage, with an opening closed by a glass plate. The stream issuing from the ajutage, describing a parabola in its course to the tub below, a beam of electric light, directed through the glazed opening and the contents of the vessel, follows the course of the jet from point to point, so that the entire jet becomes luminous and sparkling, the red colour of molten cast-iron being communicated by making the glass through which the light is transmitted to the water of an orange-red tint. The fireworks ignited in the tub to produce the flame previously mentioned are believed to have been set off by pellets of potassium, fired by contact with the water in the manner very generally known. A foreign contemporary suggests that a similar application might be made of the recent discovery by Professor Nickels—that, if commercial chloride of copper be mingled with sulphide of carbon holding phosphorus in solution, the mixture will only smoke, whereas the addition of a little ammonia (either gaseous or aqua ammonia) will insure its instantaneous bursting into flame. It was by means like this that, in the old times, sorcerers wrought their wonders to the astonishment alike of kings and people; but, in these days, the stage-carpenter enables, for a few dimes, miracles to be witnessed for amusement that, a few generations ago, would have filled multitudes with awe.—*American Artisan.*

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the Chemical News, *with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."*

Note. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, November 15, 1869.

This number contains the following original memoirs and papers relating to chemistry and allied sciences.

Researches on the Luminous Effects Due to the Action of Light upon Different Bodies—Refrangibility of the Active Rays.—M. Becquerel.—This is the fifth instalment of a lengthy memoir on this subject. In order to study very completely the mode according to which the exciting action (*action excitatrice*) of the solar spectrum is distributed when made to illuminate bodies not possessed of any great phosphorescence, the author applies a wide-mouthed phosphoroscope. The substance to be investigated is reduced to a fine powder, and fixed, by means of a little gum-water, to a plate of mica. The author's experiments led to the following conclusions:—The most refrangible rays, and principally those beyond the violet, are the most active; the different parts of the solar spectrum differ in their activity; the least refrangible rays from the blue, and past the ultra-red, act especially as extinguishers of phosphorescence.

Petroleum in the Netherlands' East Indies.—Dr. von Baumhauer.—The author gives a complete description of a large number of sources of petroleum discovered in different islands of the Indian Archipelago, which are dependencies of the Netherlands. The author states that, from observations and experiments made, there exists, at 250 metres' depth, an almost inexhaustible reservoir of this fluid.

Facts relating to Interverted Sugar.—M. Maumené.—The so-called interverted sugar is prepared by the author in the following manner:—Perfectly colourless sugar-candy is pulverised and thoroughly washed, first, with pure ether, and then with perfectly pure absolute alcohol; the powder is next dissolved in about five times its weight of very pure distilled water, to which is added 1 c.c. of pure concentrated hydrochloric acid (this quantity of acid is sufficient for the conversion of 1 kilo. of pure sugar). The aqueous solution is heated on a water-bath for a few hours, until colouration just begins to be perceptible. The HCl is removed, by the quantity of oxide of silver required for that purpose, with only five milligrms. excess; the chloride of silver is

separated by filtration; the filtered liquid treated with sulphuretted hydrogen, to make perfectly sure of the removal of all metal; the liquid again filtered, and next evaporated upon a water-bath, yielding perfectly pure glucose. The remainder of this paper is a critical review of M. Dubrunfaut's labours, and too lengthy to admit of any useful abstraction.

Lower Lignites of the Plastic Clay of the Paris Basin.—M. Planté.—An interesting paleontological paper.

Chemical Composition and Mode of Deposition of the Layers of the Great Oolite and Forest Marble in the Haute-Marne.—M. Guignet.—After referring, at some length, to the peculiar geological features of this portion of France, the author communicates the analysis of a peculiar kind of soil, which, in 100 parts, consists of—Silica, 50·0; alumina, 15·0; peroxide of iron, 10·0; lime, 2·5; water, 5·0; magnesia, manganese, sulphuric acid, and other non-determined substances, 17·5; the greater portion of this paper is chiefly of local interest.

Permanganic Acid.—M. Delaurier.—After briefly referring to former communications on this subject, the author states—Manganate of lime is produced by heating, with access of air, 1 equiv. of peroxide of manganese, and 1 equiv. of lime. This compound exhibits a brown colour; and when the ignition is continued, the mixture, being stirred to promote the access of air, it is converted into permanganate of lime, exhibiting a blackish colour, and being more fusible than the manganate—

$$2CaO,MnO_3+O=CaO,Mn_2O_7+CaO.$$

This substance is a powder; and when the author tried to set free permanganic acid from it, by means of 2 equivs. of sulphuric acid diluted with some water, the heat thereby disengaged is too great, and the permanganic acid is decomposed into sesquioxide of manganese and oxygen; but when fused permanganate of lime is applied, the action of the sulphuric acid is slow, and the permanganic acid may be obtained by distillation at a temperature of from 60° to 70°.

This number contains several papers relating to meteorology and luminous meteors—among these, a lengthy account, accompanied with an engraving, of a bolide and its explosion, observed by M. J. Silbermann on the 11th inst., at nearly 11 p.m.

Annalen der Chemie und Pharmacie, October, 1869.

This number contains the following original papers and memoirs:—

Researches on the Essential Oil of the Fruits of Heracleum Spondylium.—M. Zincke.—The essential oil was obtained by distilling, with water, the fruits of the *Heracleum spondylium*. 80 lbs. of the fresh fruits yielded 120 grms. of oil; the water which came over with the oil exhibited a very strongly acid reaction to test paper, and was, therefore, also subjected to investigation. The essential oil which was obtained was of a bright green colour, very fluid, and exhibited only a slight smell, which was rather pleasant; its taste was burning and acrid; sp. gr. at 20°, 0·864; slightly acid reaction to test paper; did not yield, when treated with a concentrated solution of bisulphite of soda, any crystalline substance (stearopten); submitted to fractional distillation, there were obtained two portions—one (about 14 grms.) came over at from 190° to 195°, the other portion (of about 40 grms.) came over at 206° and 208°. This last portion exhibited a perfectly clear neutral fluid, insoluble in water, but miscible with alcohol and ether; sp. gr. at 16°, 0·8717; formula, $C_8H_{10}O$. This portion of the oil turned out to be, on further investigation, an octyl-alcohol; formula, $C_8H_{18}O$. The following derivatives of octyl-alcohol were investigated:—Chlorooctyl, $C_8H_{17}Cl$; bromooctyl, $C_8H_{17}Br$; iodooctyl, $C_8H_{17}I$; octylic acid-octyl ether, $C_8H_{17},C_8H_{15}O_2$; benzoic acid-octyl ether, a colourless fluid, exhibiting an aromatic odour, boiling at about 306°, insoluble in water, but readily soluble in alcohol and ether. The investigation of the first portion of the oil (boiling between 190° and 195°) proved it also to contain an octyl-alcohol, but along with it some substances the nature of which could not be ascertained with certainty. The acid-water above alluded to was found to contain acetic and capronic acids.

Synthesis of a Hydrocarbon of Ethyl-Vinyl isomeric with Butylen.—M. Wurtz.—In order to prepare hydrocarbons synthetically, the author causes zinc ethyl to act upon organic bromine or iodine compounds. Zinc ethyl and bromated ethylen are mixed, and heated to 140° in sealed tubes, and next left standing for several weeks. Previous to opening the tubes, these should be placed in freezing mixture, and the gas which is given off when the tubes are opened is made to pass into broming. The bromated compound thus obtained is a perfectly clear liquid, boiling at 166°; sp. gr., 1·876. When this bromated compound is treated with sodium, ethyl-vinyl is set free; this substance is a fluid boiling at −5°.

Researches on the Constitution of Piperine and its Products of Decomposition, Piperinic Acid and Piperidine.—MM. Fittig and Mielch.—This memoir, of which the first instalment is here given, is divided into the following sections:—1. Preparation and properties of piperinic acid.—This acid is prepared by gently boiling, for about twenty-four hours, a mixture of 1 part of piperine, 1 part of caustic potassa, and 5 parts of alcohol, yielding piperinate of potassa. The authors have tried to split up piperine by means of hydrochloric acid; this method, however, proved unavailable, since there were by-products formed which destroyed nearly all the piperinic acid. Piperinic acid, when pure, is a colourless solid substance, fusing between 212° and 213°; when submitted to distillation along with excess of lime, phenol is among the products of the decomposition. 2. Experiments made in order to solve the question whether piperinic acid contains HO or CH_2O, C_2H_2O, &c.—From the lengthy series of experiments instituted by the authors, the conclusion is that piperinic acid is a monobasic, as well as a monatomic acid. 3. Products of the oxidation of piperinic acid.—(*a*) Behaviour of piperinic acid towards chromic acid. (*b*) Behaviour of piperinic acid with permanganic acid in neutral solution. Piperonal is one of the chief products of the oxidation of piperinic acid; formula of piperonal, $C_8H_6O_3$. Piperonylic acid, $C_8H_8O_4$, stands in the same relation to piperonal as benzoic acid to oil of bitter almonds. (*c*) Action of nascent hydrogen gas upon piperonal and piperonylic acid. (*d*) Piperinic acid and nitric acid. 4. Action of bromine upon piperinic acid. 5. Hydro-piperinic with oxidising substances and bromine.

Researches on the Creosote obtained from Rhenish Beech-Wood Tar.—M. Marasse.—From the introduction to this paper, we learn that there exists some difference between the creosote obtained from beech-wood grown along the Rhine and that grown in a portion of Southern Germany. Both kinds of creosote contain guaiacol, $C_7H_8O_2$, and cresol, $C_8H_{10}O_2$, and, moreover, in addition thereto some other substances not containing oxygen. The author's researches on the Rhenish beech-wood tar prove that there are contained in that liquid—guaiacol, cresol, phenyl-alcohol, and substances homologous therewith. The lengthy essay is divided into the following sections:—(*a*) Researches of the fluids boiling below 199° (the raw material operated on was a rectified creosote of commerce of excellent quality, manufactured by MM. Dietze and Co., operative chemists, at Mainze); (*b*) action of powdered zinc upon creosote boiling between 200° and 203°; (*c*) action of fusing caustic potassa upon creosote of the same boiling point; (*d*) action of hydrochloric and hydriodic acids upon that same creosote; (*e*) preparation of the methylic ether of cresylic alcohol and of the neutral methylic ether of pyrocatechin; (*f*) action of hydriodic acid upon creosote boiling at between 217° and 220°; (*g*) action of hydrochloric acid and chlorate of potassa upon guaiacol; (*h*) action of the last-named chemicals upon creosote boiling at between 200° and 203°. The author of this paper adds a foot-note, of the following purport:—It is generally taken for granted that the use of chromate of lead, in the elementary organic analysis, is preferable to that of oxide of copper whenever the complete combustion of difficultly-combustible substances has to be provided for; but the author found that in the case of cresylic alcohol (even when a current of oxygen is made to pass through the combustion-tube towards the end of the operation), its complete combustion is impossible. As the cause for this phenomenon, the author assigns the fact that a portion of the chromate of lead is entirely reduced to the metallic state, and that this lead retains carbon, preventing its combustion. It is, perhaps, not out of place here to observe that this same observation was made about thirty years ago by the late Berzelius, who therefore advised the admixture of pure and carefully-fused bichromate of potassa in small quantity to the chromate of lead.

Products of the Oxidation of Toluol-Sulpho Acid by Fusing Caustic Potassa.—M. Barth.—The author obtained, by this reaction, paraoxybenzoic acid, salicylic acid, cresol, and other substances. Paraoxybenzoic acid fuses at 210°, and crystallises in prismatic-shaped large white-coloured crystals; formula, $C_7H_6O_3+H_2O$.

Constitution of Phloretinic Acid and Tyrosine.—M. Barth.—When phloretinic acid is submitted to fusion along with excess of caustic potassa, the author obtained a substance, $C_7H_6O_2+H_2O$. On further investigation of this subject, the author came to the conclusion that there exist two acids—

$$C_6H_4\begin{cases}OH\\C_2H_3O_2\end{cases}$$

each of which yields, on becoming oxidised, paraoxybenzoic acid. Tyrosin, when pure, also yields, on fusion with caustic potassa, the same acid. The theoretical reasonings of the author, concerning the constitution of tyrosine—

$$C_6H_3\begin{cases}OH\\NH.C_3H_5\\COOH\end{cases}$$

are too abstruse to be suitable for abstraction.

Decomposition of Acetate of Silver under the Influence of Iodine and a High Temperature.—M. Birnbaum.—After reviewing the labours of MM. Weltzien, St. Claire-Deville, Bourgoin, and others who have experimented on this subject, the author states that he obtained, by causing iodine to act upon acetate of silver, chiefly two substances—viz., a fluid, and a mixture of gas, chiefly carbonic acid; the fluid is acetic acid, while among the gases elayl and acetylen could be readily detected. When the rather violent reaction is moderated, the author found that the following products are formed:—Iodide of silver, acetate of methyl, acetic acid, carbonic acid, acetylen, hydrogen, and sometimes silver and carbon. The quantities of these substances vary considerably, and it is the author's opinion that this should indicate that several reactions are going on at the same time. The reaction may be represented by the following formula:—

$$2CH_3COOAg+I_2=CH_3COOH+CH_2+CO_2+2AgI;$$

$$2CH_2=C_2H_2+H_2.$$

Acetate of silver, when in aqueous solution, behaves with an aqueous solution of iodine in a different manner, and the reaction is expressed by the following formula:—

$$6C_2H_3AgO+6I+3H_2O=6C_2H_4O_2+5AgI+AgIO_3.$$

On Sulphate of Amarine.—M. Groth.—The author first refers to M. Laurent's researches on this subject, and then says that he could only experiment with a very small quantity of the above-named substance, which had been forwarded to him more for crystallographical than for chemical research. Sulphate of amarine is tolerably soluble in water; its water of crystallisation is driven off at about 210°; composition, $2(C_{21}H_{12}N_2)2SO_4+7aq$.

Formation of Phenols when Chloride of Zinc Acts upon Camphor.—M. Rommier.—According to the late M. Gerhardt

camphor is converted into cymen and water by distillation with chloride of zinc, according to the formula $C_{20}H_{16}O_2=C_{20}H_{14}+2HO$. Very many experimenters—among them, MM. Lippmann, Longuinine, Fittig, &c.—have found it either impossible, or, at least, very difficult, to obtain this result. The author states that he operated with 2 kilos. of camphor, and obtained about 700 grms. of a volatile oil boiling between 140° and 240°; this oil proved to be a mixture of various substances, among which were cresyl-alcohol, several hydrocarbons, and other products of decomposition, due rather to the high temperature than to the simple elimination of water by the chloride of zinc and high temperature together.

Conversion of the Butyric Acid of Fermentation into Normal Primary Butyl-Alcohol, and into Ordinary Butyl-Alcohol as obtained by Fermentation.—M. Linnemann.—This is only a brief preliminary notice written *pour prendre date*.

Cosmos, November 13, 1869.

This periodical contains the following original papers and communications:—

Estimation of Nickeliferous Iron in Meteoric Stones.—M. Meunier.—There are three methods chiefly in use for this purpose—viz., separation of the metal by means of a magnet; solution of the metal in a solvent, which leaves the remainder of the material composing the stone untouched; and the measuring of the hydrogen set free by the solution of the metal in a confined space. The author has added to these methods of estimation another, which he describes as follows:—When the meteorite to be investigated is very finely pulverised in an agate mortar, there is added to it an excess of a solution of chloride of gold in water, the iron (present in the form of minute particles) is rapidly dissolved, and there is formed a precipitate of metallic gold equivalent to the quantity of iron present. The solution of the iron takes place rapidly, so that after a few minutes the operation is complete. The contents of the small flask, wherein the operation took place, are placed on a filter and thoroughly washed with water until the excess of chloride of gold is washed out. When this point has been arrived at, the remainder upon the filter is washed with moderately dilute hydrochloric acid, in order to remove the last traces of any chloride of gold adhering to the stony matter of the meteorite; this having been done, the residue on the filter is removed to a small flask, and therein treated with *aqua regia* (nitro-hydrochloric acid), and the quantity of gold estimated in the liquid by well-known methods. By multiplying the weight of the gold thus obtained by the rapport of the equivalents of gold and iron, that is to say, by—

$$\frac{28}{98{\cdot}18} = 0{\cdot}286$$

the weight of nickeliferous iron is obtained. The author states that he has tested this process, and compared it with the others above alluded to, and found it to yield very correct results.

Quino-Picric Acid.—MM. Duguet and Perret.—A golden-yellow coloured substance, exhibiting a very bitter taste, difficultly soluble in water, but readily in alcohol; also soluble in ammonia and the aqueous solutions of alkalies, without decomposition; not perceptibly acted upon by daylight and air when placed in closed bottles. When projected on burning coals, this substance burns off like lycopodium, but does not detonate; on being ignited on platinum foil, no residue is left if the substance is pure. The composition of this material, which is applied as a febrifuge, is stated to be, in round numbers—Alkaloids, 58; picric acid, 42. It is manufactured by acting with picric acid upon those alkaloids of the *cinchonæ* species (viz., quinidine, quinicine, cinchonine, cinchonicine, &c.), which are not used as medicine by themselves, and, in a sense, valueless.

Annalen der Physik und Chemie, von Poggendorff, No. 10, 1869.

This number contains the following original papers:—

Thermo-Chemical Researches.—M. Thomsen.—This is the second instalment of a lengthy memoir. This portion treats of the hydracids of chlorine, bromine, iodine, fluorine, and cyanogen.

Combinations of Alcohol and Water.—M. Mendelejeff.—The second and concluding part of a very lengthy essay on a subject which is of very great importance, both in a scientific and practical point of view, in consequence of the excise duty on spirits. In this portion of the paper, a chapter is devoted to absolute alcohol. After referring to the discrepancies of the specific gravity of that fluid, as determined by different experimenters, the writer proceeds to state that he has reviewed this subject entirely, taking care to obtain alcohol chemically pure (a far more difficult problem than is generally believed); next, also, avoiding, or, at least, taking into account, the very rapid absorption of water and air (absolute alcohol absorbs air readily—100 volumes of that fluid absorb, at 15°, and 760 m.m. barometer, 10·1 volumes of nitrogen and 6·3 volumes of oxygen). The author found the specific gravity of pure absolute alcohol to be 0·79845 at $\frac{20°}{4°}$ C. In order to dehydrate the alcohol, the following substances were tried:—Potassa, chloride of calcium, dried sulphate of copper, anhydrous oxide of barium, sodium-amalgam, and quicklime; the latter is the substance best suited for that purpose. The paper further contains chapters on the contraction of mixtures of alcohol and water, and on the changes of specific gravity of mixtures of alcohol and water.

New Sulpho-Salts.—M. Schneider.—Sulphide of silver and sulphide of iron, $Ag_2Fe_2S_3$; in 100 parts—Silver, 47·38; iron, 24·56; sulphur, 28·06. This compound exhibits the following properties:—Iron-grey coloured shiny crystalline needles, unaltered in dry air, but becoming rapidly rust-coloured when exposed to moist air; not acted upon by very dilute hydrochloric acid, but becoming rapidly decomposed by the action of stronger acid, sulphuretted hydrogen becoming evolved. Heated in a dry glass tube, this compound fuses, and vapours of sulphur are given off, leaving a residue consisting of protosulphuret of iron and metallic silver. Sulphide of sodium with sulphide of iron, containing water, $Na_2Fe_2S_4+4H_2O$; in 100 parts—Sodium, 12·43; iron, 31·07; sulphur, 35·44; water, 19·58. Sulphide of sodium with sulphide of bismuth, $Na_2Bi_2S_4$; in 100 parts—Sodium, 7·79; bismuth, 70·51; sulphur, 21·70. Cuprosulphide of sulphide of potassium with sulphide of copper, $K_2Cu_2S_2$; in 100 parts—Potassium, 10·05; copper, 65·27; sulphur, 24·68. Disodium-cuprosulphide with sulphide of copper, $Na_2Cu_2S_2$; in 100 parts—Sodium, 13·84; copper, 57·29; sulphur, 28·87. Potassic-sulphide of iron with sulphide of copper, $K_2FeCu_2S_4$; in 100 parts—Potassium, 17·28; iron, 12·37; copper, 42·08; sulphur, 28·27. Ferro-sodium-sulphide of copper with sulphide of copper, $Na_2FeCu_2S_4$; in 100 parts—Sodium, 10·94; iron, 13·32; copper, 43·50; sulphur, 31·44.

Emission and Absorption of the Heat-Rays Emitted by Bodies at Lower Temperatures.—M. Magnus.—The main points of this paper are:—Different bodies, heated to 150°, emit different kinds of heat; some substances only emit one kind of heat—others, again, various kinds. Pure rock-salt is monothermic; sylvin (chloride of potassium) behaves in a similar manner.

NOTES AND QUERIES.

Bisulphite of Lime.—(Reply to "A. N. Palmer.")—This substance is made by passing a current of sulphurous acid gas into milk of lime until a clear liquid is obtained and the lime dissolved. Care should be taken to wash the sulphurous acid.

Shoddy.—(Reply to "Child.")—Use nitric acid; this will have the effect you desire, of reducing the woolly substance to a pulpy mass converting it into xantho-proteic acid, which is valuable as manure. By applying the acid named, you can somewhat reduce the quantity of sulphuric acid for dissolving phosphates.

Aluminium Sulphide and Phosphide.—I wish to obtain a small quantity of sulphide and phosphide of aluminium, and should feel greatly obliged if you could inform me where it is probable I could obtain them. I have tried most of the London retail houses, but without success, neither have I been successful in making these compounds, though following the methods described in Watts's "Dictionary," vol. i., rather strictly. Perhaps you could likewise inform me where I could find the processes described in greater detail.—D. H.

The Atomicity of Aluminium.—Would some kind reader oblige an intending candidate for examination by communicating the most rational view of the atomicity of aluminium? Miller classes it as a triad, while Williamson states it to be of "even atomicity;" Roscoe called it tetratomic, but has withdrawn that assertion from his last edition. Messrs. Mottershead profess to follow Roscoe in their chemical labels, but give the symbol for alum $Al(NH_4)_2SO_4+12H_2O$; This, I presume, is a misprint (though still remaining uncorrected); but why should the single formula be given, instead of the double one of the books?—DUBITANS.

By-Products Containing Soluble Phosphates.—(Answer to "Arthur Warner").—It is not at all likely you will meet with any such by-product, unless, perchance, in the mother liquor of phosphate of soda manufacture; but phosphoric acid is too valuable a substance to be negligently dealt with. There is a method of extracting gelatine and glue from bones, whereby the latter are first treated with a moderately strong hydrochloric acid which dissolves the mineral matter of the bone, and, consequently, contains all the phosphates thereof in soluble state; but where you could obtain such liquor we are unable to say; perhaps glue and size makers would be able to inform you.

MEETINGS FOR THE WEEK.

MONDAY, 29th.—Medical, 8.
—— London Institution, 4.
TUESDAY, 30th.—Royal, 4. Anniversary.
WEDNESDAY, Dec. 1st.—Society of Arts, 8.
—— Pharmaceutical, 8.
THURSDAY, 2nd.—London Institution, 7.30.
—— Chemical, 8.

TO CORRESPONDENTS.

Tallow Melter.—Please forward your address, as a letter is waiting for you at our office.

E. H. & Co.—You can learn particulars about the automatic steam-boiler feeding apparatus with constant level by writing to M. E. Leroux, 11, Rue des Beaux-Arts à Paris.

An Old and Regular Subscriber.—Address to M. Théodore Péters, fabricant de couleurs d'aniline et d'orseille, Chemnitz, Saxony.

F. Sutton.—Received, with thanks.

Enquirer.—(1) L. Oertling, 27, Moorgate Street, E.C. (2) None but good ventilation.

M.—See Eggertz's process, given in the CHEMICAL NEWS a short time back.

R. R. Tatlock.—Received, with thanks.

THE CHEMICAL NEWS.

VOL. XX. No. 523.

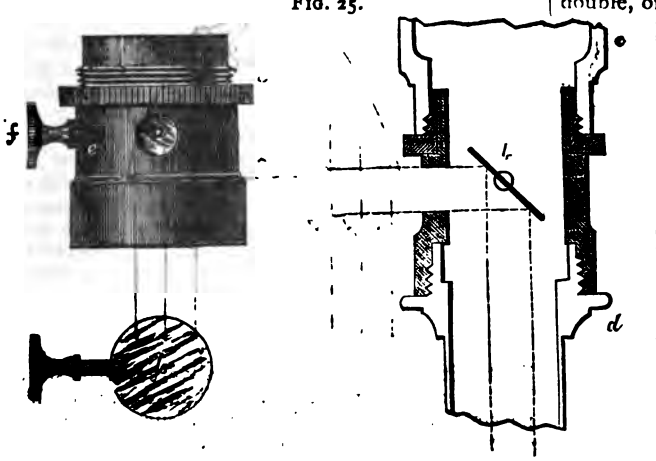
ON MICROSCOPICAL MANIPULATION.*

By W. T. SUFFOLK, F.R.M.S.

(Continued from p. 256.)

A MEANS of illumination adapted for use with objectives of high power, in which the space above the object is too small to admit of light being thrown upon it by any of the apparatus just described, has been contrived by Professor H. L. Smith, of Kenyon College, Ohio. He uses the object-glass itself as a condenser. A pencil of light is admitted through an aperture in the side of an adapter screwed on to the body of the microscope, which contains a small silvered mirror with suitable adjustments for reflecting the pencil downwards through the object-glass which is attached below the adapter. This apparatus was sent to Mr. E. G. Lobb, of the Royal Microscopical Society, and exhibited at the meeting in January, 1866. The instrument was placed in the hands of Messrs. R. and J. Beck and Messrs. Powell and Lealand, who each produced an improved modification. For the silvered mirror of Professor Smith they both substituted an unsilvered glass surface; that of Messrs. Powell and Lealand was a piece of parallel surfaced glass, fixed at an angle of 45°; Messrs. Beck used a disc of thin cover glass (Fig. 25, *b*), and allowed the angle to be altered at pleasure by means of a milled head, *f*, passing through the aperture, *e*. The light of a lamp is directed through the hole, *a*, in the adapter, and forms an image of the flame on the object when the object-glass is in focus. The lamp should be placed at a distance of about eight inches from the instrument; sometimes a condensing lens may be placed between the lamp and microscope with advantage. The manipulation with the instruments of both makers is precisely similar. The objects to be viewed with this illuminator should be uncovered, otherwise the cover reflects nearly the whole of the light, and scarcely any falls upon the object; some light is also lost by reflection on its passage upwards through the oblique unsilvered mirror. The impossibility of obtaining a satisfactory view of a covered object will most probably prevent this instrument from coming into very general use, although it affords valuable information to those who will take the trouble to master the difficulties attending its use.

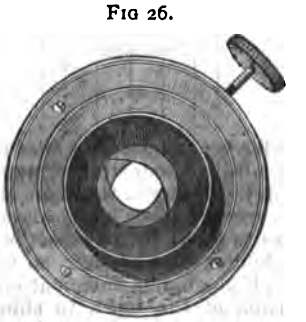
FIG. 25.



The second class of illuminators, those which are placed beneath the stage, are also very numerous. The most familiar is the *mirror*, which forms a part of every microscope. A great variety of illumination may be obtained from the mirror alone, if properly mounted so that it may be turned considerably aside. The mirror of many microscopes is now placed on a double-jointed arm, which permits very oblique illumination to be obtained. In order to understand practically the difference caused by the position of the mirror, the student is recommended to examine a diatom of moderate difficulty, such as *Pleurosigma angulatum*, with a good ⅓ or ¼ objective, which should be accurately adjusted for the thickness of the cover glass, and a deep eye-piece should be used. It will be found, when the light is central, that none of the usual markings will be visible; but when the illuminating pencil falls very obliquely, the *apparent* cross lines (?) will come into view. With the better class of microscopes, the mirror is usually made double, one side concave and the other plane; the plane mirror is used for reflecting daylight when the greatest intensity is not required, and for use with the achromatic condenser and parabolic reflector (Wenham's), and in all other cases when parallel rays are needed. The concave mirror acts in some degree as a condenser, and is to be used with lamp light and when it is required to make daylight more intense. The *diaphragm plate* is used in combination with the mirror to regulate the angle of the pencil; this can, however, be done with much greater nicety by employing the graduating diaphragm of Mr. Collins (Fig. 26) or the very beautiful iris diaphragm of Messrs. Beck (Fig. 27), both of which allow the aperture under the stage to be gradually diminished or enlarged without the interval of darkness which occurs during the shifting of the ordinary wheel of diaphragms.

A very useful illumination, resembling the light of a *white cloud*, may be obtained by placing a piece of white paper over the mirror, and concentrating the light of a lamp upon it by means of the con-

FIG 26.



* The substance of a course of lectures delivered to the members of the Quekett Microscopical Club, January—April, 1866.

Hence there is only one fixed term of solubility, namely, that given by the 10-atom salt, and represented by 1120 at 18° C. Whatever modifications are produced in the solutions by means of temperature or supersaturation, the mother liquor always returns, after the lapse of sufficient time, to this normal, fixed density of 1120.

In considering the abnormal solubility of the anhydrous salt, whether obtained by drying or fusing the 10-atom variety, and in comparing the amorphous state of this salt with sugars in the state of supersaturation, are we not led to conclude that the molecular constitution of the anhydrous sulphate has the same constitution as that of the sugars in supersaturated solutions?

The depression in temperature which accompanies solution implies a transfer of heat into molecular mechanical work under the conditions of supersaturation. When this state ceases, the temperature rises, implying an inverse transfer of mechanical work into heat, in consequence of the return of the saline molecule to its primary constitution.

The facts of superfusion and supersaturation are well explained by changes in physical and chemical constitution brought about by fusion or solution, the two molecular conditions being, probably, the crystalline and the amorphous.

Such are M. Dubrunfaut's views, which I have endeavoured to give in a condensed form. M. Margueritte replied, on June 7th, that M. Dubrunfaut's hypotheses are contradicted by experiment. Crystallised sugar may form supersaturated solutions in dilute alcohol, and still preserve intact its optical properties, and, therefore, the identity of its constitution, a fact which proves that the increased transitory solubility of a body is not the effect of a molecular change or of an isomeric modification.

The same number of the *Comptes Rendus* contains also a note by M. Lecoq de Boisbaudran, in reply to M. Dubrunfaut. After some remarks on change of structure by means of fusion, which produces modifications similar to those which result from solution, he admits that Löwel's hypothesis rests on facts observed under conditions when supersaturation no longer exists. While not agreeing with M. Dubrunfaut, he does not insist on his own hypothesis; and, although optical tests fail in the case of sodic sulphate, yet an experiment with chrome alum shows the co-existence of two different modifications in a definite state of solution. Dissolve chrome alum in the cold, and the solution has a blue-violet colour; dissolve the same salt in boiling water, and the solution is dark green. If the two solutions be exposed to the ordinary temperature, the blue solution soon loses a little of its purity, and tends to become greenish, while the green solution tends to become bluish, until at length the two solutions pass into the same green-blue colour, which represents the intermediate state between the initial modifications.

M. Lecoq de Boisbaudran cannot understand M. Dubrunfaut's object in undertaking new experiments on the density of the mother liquors of sodic sulphate, since it has long been known that, by exposure to the air, the 10-atom salt is produced from the various solutions, and that, under like conditions of temperature and saturation, the densities must be equal. If M. Dubrunfaut had operated on the anhydrous salt without exposure to the dust of the air, he would have obtained a stronger mother liquor. When a supersaturated solution resting on an excess of the anhydrous salt is suddenly solidified by contact with a crystal of the 10-atom salt, the mother liquor of the anhydrous salt is much richer than the mother liquor of the 10-atom crystals. He believes that the solubilities of all three varieties of the same salt to be equally normal. The solubility of a body ought to be definite under determined physical conditions (temperature, pressure, &c.); but, if such body is in the presence of one of its more stable modifications, this will destroy the initial modification, and we should certainly fall into error in attributing to the primitive body the observed solubility.

M. Dubrunfaut, abandoning the hypothesis which supposes the 10-atom sodic sulphate to exist as the 7-atom in solution, now supposes the anhydrous salt to be in solution. The objections to the opinion that only the 7-atom salt is in solution apply with even more force to the new proposal to make the anhydrous salt play the same part.

Such is the state of the question at the present time among the French chemists whose views are reported by the Academy. The favourite view of supersaturation, both in French as well as English, American, and, I may add, German text-books, is Löwel's—namely that a solution (say of sodic sulphate) saturated at a high temperature, and left to cool in a close or loosely covered vessel, does not actually become supersaturated, but undergoes a molecular change, in which the 10-atom salt becomes the more soluble 7-atom; so that, instead of having a supersaturated solution of the 10-atom salt, we have only a saturated solution of the 7-atom. When, however, under the influence of some mysterious catalytic action, crystallisation is about to set in, the solution suddenly recovers the molecular constitution of the 10-atom salt, as well as its solubility, and the 10-atom salt is thrown down.

All this is very ingenious. The most remarkable circumstance connected with the Löwel hypothesis is that Löwel was himself the first chemist who called it in question. The facts are these:—Löwel's first memoir appeared in 1850; his fifth in 1855; in all of which he maintains the molecular theory above stated in the case of sodic sulphate, and a similar theory with respect to two other salts—viz., the sodic carbonate and the magnesia sulphate. But, in 1857, he published a sixth memoir, in which he strongly inclines to the opinion that, within the limits of a considerable range of temperature, sodic sulphate in solution is in the anhydrous condition. His views will be given in another article.

Highgate, N., November 22nd, 1869.

ON THE

COMBINATIONS OF PHOSPHATE OF LIME AND SULPHUROUS ACID.*

By Dr. B. W. GERLAND, Macclesfield.

PHOSPHATE of lime, in whatever state it may be, readily dissolves in an aqueous solution of sulphurous acid. The solution can be obtained of great strength; thus, from freshly-precipitated tribasic phosphate of lime, a liquor was prepared of 1·3 specific gravity; and, from bone-ash, one of 1·1708 specific gravity. The former contained, in 1000 c.c.—

	grms.
Sulphurous acid	218·38
Sulphuric acid	0·70
Lime	101·79
Phosphoric acid	82·89
	403·76

These figures agree tolerably with the formula—

$$3CaO,PO_5+6SO_2,$$

as the comparison with the calculated table shows—

$3CaO$	84	98·20
PO_5	71·4	82·89
$6SO_2$	192	224·45
		405·54

* Read before the Manchester Literary and Philosophical Society, Nov. 16th, 1869.

The solution of bone-ash, in sulphurous acid of 1·1708 specific gravity, was found to contain, in 1000 c.c.—

	grms.
Sulphurous acid	141·82
Sulphuric acid	trace
Phosphoric acid	47·42
Magnesia	2·79
Lime	59·69
	251·72

The formula $3CaO,PO_5,6SO_2$ requires, for 47·42 PO_5—

	grms.	
Lime	55·78	
Phosphoric acid	47·42	
Sulphurous acid	127·50	
		230·70
The excess of lime in the analysis is		3·91
and magnesia		2·79
These two would require sulphurous acid		8·73
Excess of sulphurous acid		5·58
		251·71

The bone-ash which was left undissolved by the sulphurous acid had lost all its magnesia, a circumstance which accounts for the large amount of magnesia in the liquor.

The proportion of $3CaO,PO_5$ and SO_2 varies according to the strength of the liquor; if the latter is, for instance, 1·060 specific gravity, 5eq SO_2 dissolve $3CaO,PO_5$; and, in still weaker solutions, we find only 4eq SO_2 for $3CaO,PO_5$.

These solutions possess very interesting reactions, some of which are the following.

A neutral solution of ferric chloride precipitates straw-coloured phosphate of iron, and, if added in proper quantity, the liquor is free from both iron and phosphoric acid. The precipitate, after washing and drying over sulphuric acid, is free from lime and sulphurous acid. Its analysis agrees well with the formula Fe_2O_3,PO_5+5HO.

Acetate of copper colours the sulphurous acid solution, when added in small quantity, intensely green; a further addition produces a thick yellow precipitate, which rapidly changes in contact with air, and thereby becomes green. Acetate of lead also produces a thick precipitate of white colour. These precipitates contain, besides the metallic oxide, lime, phosphoric and sulphurous acids. Chloride of barium precipitates the solution directly, and chloride of magnesium after some standing.

The solution of phosphate of lime in sulphurous acid possesses the taste and smell of the acid, but to a much smaller extent than an aqueous solution of the acid containing the same amount of sulphurous acid.

Under the influence of boiling heat, the phosphate solution is decomposed slowly, sulphurous acid escapes, and a heavy white crystalline precipitate is formed. Under the microscope, it appears as composed of crystals of the hexagonal system, like those of rock-crystal. Washed and dried over sulphuric acid, it contained—

Sulphurous acid	15·61
Sulphuric acid	0·23
Lime	39·89
Phosphoric acid	34·48
Water	9·08
	99·29

These numbers agree with the formula—

$$3CaO,PO_5,SO_2,2HO,$$

the calculated numbers of which are—

SO_2	32		15·58
$3CaO$	84		40·89
PO_5	71·4		34·76
$2HO$	18		8·77
	205·4		100·00

This sulphited phosphate of lime has no smell or taste, and is distinguished from all sulphites by its stability. Heated in an air-bath for three hours to 130° C., it lost 0·64 per cent of water; but the amount of sulphurous acid remained unchanged, neither had a humid atmosphere the slightest effect upon it. The water is held in intimate combination, and is only expelled at a higher temperature when it is accompanied by fumes of sulphur, sulphuric and sulphurous acids. The residue contains, besides lime and phosphoric acid, sulphate and sulphide of calcium.

Cold water has no effect upon the sulphited phosphate of lime. After long-continued boiling, the air being excluded, a partial decomposition takes place, which is shown by the following analysis.

1000 c.c. of the water contained—

	grm.
SO_2	0·2680
SO_3	0·0470
PO_5	0·1181
CaO	0·2045

And an undetermined quantity of the undissolved residue contained—

SO_2	0·03464
PO_5	0·12393
CaO	0·13916

The constituents are, therefore, in the following proportions:—

In the solution—

1 eq. PO_5 : 4·35 eq. CaO : 5·07 eq. SO_2 : 0·71 eq. SO_3;

And in the residue—

1 eq. PO_5 : 2·85 eq. CaO : 0·623 eq. SO_4.

The sulphite, which withstands the action of the atmosphere indefinitely, is rapidly oxidised when incorporated with soil. A quantity was buried in a heavy clay soil (which, as was ascertained previously, contained no lime and phosphoric acid soluble in dilute hydrochloric acid), and was exhumed after two months, when it was found to be free from sulphurous acid. The sample was selected for analysis with the least possible quantity of soil. It contained—

	per cent.
SO_3	18·59
PO_5	24·58
CaO	33·66

The oxidising process which has taken place in this instance may be expressed by the formula—

$$3CaO,PO_5,SO_2,2HO+O=2CaO,HO,PO_5+CaO,SO_4+HO.$$

The original substance contained 34·5 per cent PO_5 and 15·8 per cent sulphurous acid, equal to 19·75 per cent SO_3. The sample for the last analysis ought, therefore, to contain, for 24·58 per cent PO_5, 14 per cent SO_3; but, according to the analysis, it contains 18·59 per cent—that is, 4½ per cent more. This excess of sulphuric acid proves that it is dissolved at a slower rate than the phosphoric acid. Calculating the amount of lime which the acids of the analysis require, we find, for—

18·59 SO_3 as CaO,SO_3		13·01 per cent CaO,
And for—		
24·58 per cent PO_5 as $2CaO,PO_5$	19·28	„ „
Total	32·29	„

This number is less than the quantity of CaO found by 1·37 per cent, which excess is to be accounted for by the tendencies of the dibasic phosphate to undergo a partial decomposition under the action of water, in consequence of which a compound of higher basicity is left undissolved.

It is, therefore, evident that the new compound will, in the soil, act as a soluble phosphate of lime; it has, in fact, for several seasons been used as a manure, and has given great satisfaction.

Strong mineral acids dissolve the sulphited phosphate of lime under effervescence of sulphurous acid. Acetic acid has no effect in the cold, and dissolves it only after long-continued boiling, but much easier when the air has access. Oxalic acid decomposes it a little quicker. Chlorine gas is readily absorbed by the new phosphate. After the action is completed, it contains no more sulphurous acid, but only traces of sulphuric acid. Of the phosphoric acid, only a small portion has become soluble (about 1-12th), This decomposition still occupies my attention.

A weak solution of iodine, such as Mohr's standard solution, acts readily upon the sulphited phosphate of lime, as represented by the formula—

$$3CaO,PO_5,SO_2,2HO+I=CaO,2HO,PO_5+CaO,SO_3+CaI.$$

The colour of the iodine disappears as long as there is substance left undissolved. This is a convenient method for estimating the sulphurous acid of the compound; but, as the last portions are only slowly acted upon by the iodine, it is advisable, in order to save time, to add a drop of hydrochloric acid, when the iodine begins to disappear slowly: it does not interfere with the accuracy of the experiment.

The sulphited phosphate of lime, exposed to an atmosphere containing ammonia, rapidly absorbs the latter, but, at the same time, an equivalent quantity of sulphurous acid seems to be oxidised. A sample of the substance was placed under a glass shade with pieces of carbonate of ammonia and water for four weeks, and subsequently over sulphuric acid for two days, and yielded, by analysis, the following results:—

	per cent.
Lime	39·08
Sulphurous acid	2·50
Ammonia	5·60

The new sulphite possesses remarkable antiseptic and disinfecting powers, and, on this account, will command a general interest. The efficacy of sulphurous acid as a disinfectant is well known, and it would be more appreciated if it could be conveniently applied. The aqueous solution is expensive by transport; it is very changeable, and, in many cases, it is unavailable, on account of its pungent smell, whilst, for medical purposes, it can only be used in exceptional cases, in consequence of its irritating action. The sulphites are still more changeable. Exposed to the air, they are acted upon by carbonic acid and by oxygen; and, when mixed with decaying organic matter for disinfecting purposes, they very often increase the mischief, and sometimes cause an abundant escape of sulphuretted hydrogen. The compound of phosphate of lime with sulphurous acid has none of these disadvantages. Acids, as well as ammonia, are neutralised by it. From a sanitary point of view, ammonia is particularly objectionable: being a product of putridity, it helps to accelerate it, and also serves as a vehicle for disseminating other products which, without it, would not be volatile, or only so to a less degree.

The sulphited phosphate, when applied to putrid matter, will probably do its first service by neutralising the ammonia present (including compound ammonias), and also prevent its further formation, as the test-paper will show. The smell will soon cease, or, at least, be greatly diminished and altered, and the mass will be safe for a long time, so that it may be removed or dried without danger or inconvenience. I must here remark that large quantities of putrid matter in open spaces are more completely and speedily disinfected by small portions of the phosphate than samples in glass bottles. The compound recommends itself as a disinfectant by its physical properties. It is a clean white powder, which stains and soils nothing, dusts off garments or carpets, leaving no mark; it is free from smell and taste, and harmless to animal life.

It proves itself invaluable in stables and shippons. The air of these localities is generally highly charged with ammonia, yet the tenants are expected to live and thrive. A regular application of a small quantity of the phosphate will prevent the loss of ammonia, it will sweeten the air, and enrich the manure with phosphoric acid, thus being of threefold advantage. The loss of ammonia from the dung is not inconsiderable; it is also the most valuable constituent of it, being worth more than 9d. per lb. to the farmer.

The solution of phosphate of lime in sulphurous acid also possesses disinfecting powers, and acts, in many cases, even with greater energy than the powder. It might be used with advantage as being applicable to places which could not be reached by the other.

The neutrality, regularity of composition, utter harmlessness, and freedom from smell and taste, recommend the sulphited phosphate of lime for trial in therapeutics. It would be of interest to investigate it in relation to putrid puerperal fevers, pyæmia, &c.

It appeared to me not unlikely that a compound of phosphate of lime with 2 eq. sulphurous acid might exist. Numerous experiments, made with a view of preparing the same, have entirely failed; but some of the results are interesting as showing unexpected reactions of these compounds.

The sulphite of phosphate of lime is not acted upon by the solution of phosphate of lime in sulphurous acid. Sulphurous acid gas is only absorbed in very small proportion by either dry or wet bone-ash. This phosphate of lime is not even converted into the sulphurous acid compound by digestion with the sulphurous acid solution. If sulphurous gas is passed through water holding as excess of phosphate of lime in suspension, the latter remains unchanged.

Under the receiver of an air-pump, the sulphurous acid solution forms good sized crystals, probably belonging to the hexagonal system. Analyses of crystals of different preparations gave varying results, which, however, agreed tolerably with the formula—

$$x(3CaO,PO_5,SO_2,2HO)+y(CaO,SO_2,2HO)+z(CaO,SO_3+5HO).$$

The more crystals separate from the solution, the more the phosphoric acid accumulates in the latter. In one instance, lime, phosphoric acid, and sulphurous acid were almost in proportion of their equivalents.

Alcohol precipitates the solution of phosphate of lime in sulphurous acid. The analysis of the precipitate gave 24·8 per cent of water, and no more sulphurous acid, in proportion to lime, than the above-described powder.

The solution is also precipitated by a current of an indifferent gas, like hydrogen. The analysis of the precipitate gave figures from which no simple formula can be calculated. The amount of phosphoric acid, in proportion to the lime, is greater than that corresponding to tribasic phosphate; and the amount of sulphurous acid is much less than that of the precipitate obtained by boiling. In acordance with the foregoing, the solution, after treatment with hydrogen gas, was found to contain less phosphoric acid, in proportion to the lime, than before.

Under reduced pressure, the phosphate solution boils easier, and the separation of the precipitate takes place more readily. This precipitate contains less sulphurous acid and more water than corresponds to the formula $3CaO,PO_5,SO_2,2HO$.

I experienced so much difficulty in preparing pure tribasic phosphate of lime, that I was obliged to use, for most of my experiments, the phosphate offered by nature in bones and bone-ash.

The compounds of phosphate of lime with sulphurous acid undoubtedly possess great scientific interest. This consideration, as well as the importance they are likely to attain for agricultural and sanitary purposes, as they have now become articles of commerce, has induced me to lay before you the results obtained so far in my investigation, with the prosecution of which I am still occupied.

THE COMMITTEE OF THE BRITISH ASSOCIATION ON THE TREATMENT AND UTILISATION OF SEWAGE.

The following letter has been issued by the above committee to the municipal and sewer authorities throughout the country:—

I have the honour to inform you that, last year, at the meeting of the British Association, at Norwich, a committee was appointed to report on the treatment and utilisation of sewage. In the first instance, a grant of £10 was placed at the disposal of the committee, with which to defray the cost of printing and postage incidental to the collection of preliminary statistical information. Through the kindness of Her Majesty's Government, the committee was enabled to obtain reports respecting the methods of dealing with town refuse practised in most civilised countries; and that information has now been collected in a more complete form than hitherto existed in any country.

This preliminary work being completed, the committee was re-appointed at the meeting of the British Association this year, at Exeter; and the inquiry was considered to present such important features of social and scientific interest, that the sum of £50 was voted towards enabling the committee to enter more fully and practically upon the investigation of this subject. The British Association, being a purely scientific body, has not at its disposal funds which would be adequate or applicable for the full prosecution of this very large and pressingly-important inquiry. The committee, nevertheless, desires to take advantage of the opportunity created by the British Association to investigate the entire subject in all its bearings—whether chemical, physiological, or engineering, sanitary, municipal, or agricultural—and in a manner worthy of the body they represent.

It is unnecessary to point out the enormous importance, especially at the present time, of a full and complete investigation of this question by the light of the knowledge and experience now gained in the several departments above alluded to. But, properly to carry out such an inquiry with a practical end, numerous observations, gaugings, and experiments, aided by simultaneous analyses, are essential; and these cannot be accomplished (especially the analyses) without the continued aid of efficient and, therefore, highly-paid assistants. Moreover, from time to time, it may be necessary for the committee to purchase expensive apparatus, and to subject various inventions and processes to a thorough and complete test; for it is the desire of the committee, not only to ascertain, as far as possible, the causes of the sanitary inefficiency of existing works, but also to inquire into every suggestion which affords promise of practical utility, in order that this investigation may be searching, the report practical, and any recommendations that may be made authoritative.

It is the wish of the several members of the committee to devote, to the utmost of their ability, their personal attention to the work thus sketched out; but the expenses absolutely necessary to enable them to conduct so extended an inquiry cannot but be very heavy, and, unless they are able to secure an adequate fund, they must abandon the attempt to investigate the subject in this broad and comprehensive manner. However, since there is no subject of greater practical and social importance to the public generally, and thus to the various municipal authorities and other governing bodies throughout the country, it is believed that many will share the opinion expressed at the recent meeting of the British Association, at Exeter—that the existence of this committee affords a specially favourable opportunity for such a wide inquiry; and, for that reason, its members confidently appeal to those authorities who are officially interested in the subject to supply the funds necessary for the investigation.

I am, therefore, desired to request that you will kindly submit this letter to the body you represent; and I venture to hope you will give the committee the benefit of your good offices in procuring a subscription proportionate to the population of your town or district. . . .

I am, &c.,

George F. Barnes,
Honorary Secretary, *pro tem.*

CHLORINE AND METALLIC SODIUM.

By J. ALFRED WANKLYN, F.C.S.

When chlorine gas is passed over metallic sodium—even when the metal is fused, and, whilst in a state of fusion, shaken in contact with the gas, so as to expose fresh metallic surface—there is no action. A glass vessel containing a piece of sodium was weighed; and, after the transmission of chlorine under the circumstances above named, it was re-weighed.

	grms.
Weight before the action of chlorine ..	7·847
Weight after the action of chlorine	7·863
Gain	0·016

The quantity of metallic sodium taken for the experiment was 0·770 grm.

SPECTROSCOPIC NOTES.*

By Professor C. A. YOUNG, of Dartmouth College.

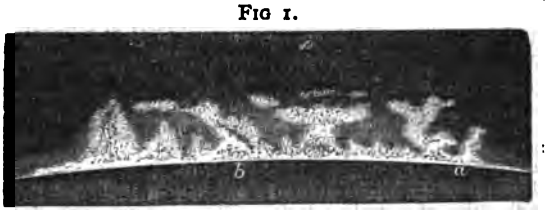
September 4th, 1869.—Prominences were noted on the sun's limb at 3 p.m. to-day in the following positions, angles reckoned from North point to the East:—

1. +70° to +100°, very straggling, not very bright.
2. −10°, large and diffuse.
3. −90°, small, but pretty bright.

September 13th, 1869.—The following protuberances were noted this p.m.

1. Between +80° and +1100, a long straggling range of protuberances, whose form was as in Fig. 1. I dare not profess any very extreme accuracy in the drawings, not being a practiced draughtsman, but the sketch gives a very fair idea of the number, form, and arrangement of the immense cloudy mass, whose height was about 50″

Fig 1.



and its length 330″ (22,500 miles by 1,350,000). The points *a* and *b* were very bright.

2. +135° small, but very bright at the base, of this form (Fig. 2.)

3. −85° of this form (Fig. 3.).

The dark spot, marked *c*, was very curious, reminding one strongly of the so-called fish-mouth in the nebula of Orion. I saw no change in it for 20 minutes. On the

* From the October number of the *Journal of the Franklin Institute*. Kindly communicated, with the cuts, by Professor Morton.

other hand, the first series mentioned were changing rapidly, so that at five o'clock the sketch which was drawn

Fig. 2.

Fig. 3.

at two was quite inapplicable, only the general features remaining unaltered.

4. −128°, about 20″ high, forked, thus :—

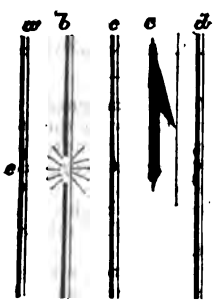
Fig. 4

The structure was *cirrus* in every one but No. 3, which seemed more like a mass of cumulus.

To-day, for the first time, I saw b_1 reversed in the chromosphere when the slit was tangent to disc; 1474 was easy; the new line at 2602 cannot be detected as yet.

At 2.25, while examining the spectrum of a large group of spots near the sun's western limb, my attention was drawn to a peculiar double *knobbiness* of the F line (on the sun's disc, not at the edge), represented by Fig. 5, *a*, at the point *e*. In a very few moments a brilliant spot replaced the knobs, not merely interrupting and reversing the dark line, but blazing like a star near the horizon, only with blue instead of red light; it remained for about two minutes, disappearing, unfortunately, while I was ex-

Fig. 5.



amining the sun's image upon the graduated screen at the slit, in order to fix its position which was at −82½, about 43″ from the edge of the limb, about 15″ inside of the inner edge of the spot-cluster. I do not know, therefore, whether it disappeared instantaneously or gradually, but presume the latter. Fig. 5, *b*, attempts to give an idea of the appearance. When I returned to the eye-piece, I saw what is represented at Fig. 5, *c*, &c. On the upper (more refrangible) edge of F, there seemed to hang a little black mote, making a *barb*, whose point reached nearly to the faint iron line just above F. As given on Angström's atlas, the wave-length of F is 486·07, while that of the iron line referred to is 485·92 (the units being millionths of a millimetre). This shows an absolute change of 0·15 in the wave-length, or a fraction of its whole amount, represented by the decimal 0·00030, and would indicate an advancing velocity of about 55·5 miles per second in the mass of hydrogen whose absorption produced this barbed displacement.

The barb continued visible for about five minutes, gradually resolving itself into three small lumps, one on the upper and two on the lower line, Fig. 5, *d*. In about ten minutes more, the F line resumed its usual appearance. I did not examine the c line, as I did not wish to disturb the adjustments and risk losing some of the curious changes going on under my eye.

After the close of this strange phenomenon, I examined, with our large telescope of 6-inch aperture, the neighbourhood in which this took place, and found a very small spot exceedingly close to, if not actually *at*, the place. This was at 2.45. At 5.30 it had grown considerably.

Undoubtedly, the phenomenon seen was the same referred to by Mr. Lockyer, when he speaks of often seeing the bright lines of the prominences not only at the sun's limb but on his disc. It is the only time I have had the good fortune to see it as yet.

The common fire-fly gives a continuous spectrum without any trace of lines, either bright or dark. It is noteworthy that this spectrum lies almost entirely between the lines C and F, the portion of the luminous diaphason where the thermal and actinic effects are nearly *nil*, and where almost all the energy expended is effective as pure light. How different from our artificial modes, in which not more than one-tenth of one per cent of the expended energy appears as light, the rest being mostly wasted in heat, and partly in actinism.

Hanover, N. H.

CORRESPONDENCE.

THE ATOMIC THEORY.

To the Editor of the Chemical News.

Sir,—Is it not surprising that, during the recent discussion on Professor Williamson's admirable paper on "The Atomic Theory," no one should have hit upon the simple link which unites the opposing doctrines?

Modern chemistry teaches us that the existence of matter as atoms and molecules is pretty nearly as certain as the existence of matter itself. It is only since that conception has been fully adopted, and by means of it, that chemistry has been raised into an exact science; and the idea involves the indivisibility of the ultimate atom.

On the other hand, mathematical science proves that such a thing as an indivisible atom having size and weight is simply an impossibility; and therefore people fear to accept the theory as absolute truth, but are compelled to use it grudgingly as a temporary expedient.

But why? both sides are correct. The atoms are the ultimate forms of matter *as we know it*, in the form of chemical elements; they cannot be divided, and remain those elements. But no one can affirm, or would think of doing so, that these elements are positively the ultimate forms of matter itself. On the other hand, there is a general feeling, justified by the remarkable relations between the atomic weights and properties of elements, that they are very probably compounds of yet simpler forms of matter, though their decomposition may not be possible to man. The doctrine of atomicity, showing us several centres of force in each atom, confirms this.

Hence, although the chemist can only deal with ascertained facts as a chemist, yet he loses none of his rights to the teachings of mathematics, and is quite entitled to believe that matter may be infinitely divisible and non-atomic in its ultimate essence, and yet be atomic and indivisible in the forms in which he has to deal with it.

May not the interplanetary ether be this ultimate form, and the tremendous actions of the sun, with its vast masses of hydrogen, be a stage of resolution of ordinary elements into this form, to be driven into space, and again condensed into ordinary matter, thus keeping up that circulation of existence which seems to be the fundamental system of Nature?—I am, &c.,

John T. Sprague.

MISCELLANEOUS.

The Royal Society.—The annual meeting of the Fellows of this Society was held on the 30th ult., at Burlington House. The President, Lieut.-General Sir Edward Sabine, K.C.B., &c., delivered the inaugural address, in which he reviewed the progress which had been made in science during the year. The following gentlemen were afterwards elected on the Council for the ensuing year, viz.:—President—Lieut.-General Sir E. Sabine, R.A., K.C.B., D.C.L., LL.D. Treasurer—William A. Miller, M.D., D.C.L., LL.D. Secretaries—William Sharpey, M.D., LL.D.; George G. Stokes, Esq., M.A., D.C.L., LL.D. Foreign Secretary—Professor William Hallows Miller, M.A., LL.D. Other members of the Council—Frederick Currey, M.A.; Warren de la Rue, Ph.D.; Sir Philip de Malpas Grey Egerton, Bart., M.P.; Professor W. H. Flower, F.R.C.S.: William Huggins; John Gwyn Jeffreys; John Marshall, F.R.C.S.; Augustus Matthiessen, Ph.D.; Capt. Richards, R.N.; the Marquis of Salisbury, M.A.; C. W. Siemens; John Simon, F.R.C.S.; Archibald Smith, M.A.; Professor H. J. Stephen Smith, M.A.; Professor John Tyndall, LL.D.; and Professor A. W. Williamson, Ph.D. The Copley Medal was awarded to M. Victor Regnault, for his researches on the specific heat of gases and vapours, &c. A Royal Medal was awarded to Sir Thomas Maclear, the Astronomer-Royal at the Cape of Good Hope, for his measurement of an arc of the meridian. A Royal Medal was also awarded to Dr. Augustus Matthiessen, F.R.S., for his researches on the electrical and other physical properties of metals and their alloys. In the course of his remarks, the President said that Dr. Matthiessen's researches were distinguished, as well for their diversity as for their uniformly complete and trustworthy character, and referred, amongst others, to his investigation of the electric conducting power of commercial copper, which had resulted in very great improvement of the conducting power of the copper wire used in submarine telegraphy. After the meeting, the Fellows and their friends dined together at Willis's Rooms. The senior Fellow of the Royal Society is Sir John F. W. Herschel, Bart., D.C.L., who was First Wrangler and Smith's Prizeman at Cambridge in 1813, and was elected F.R.S. in the same year, being then only twenty-three years of age.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, *with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."*

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, November 22, 1869.

This number contains the following original papers relating to chemistry and allied sciences:—

Spectrum of the Planet Neptune, and some Observations on Spectrum Analysis.—Rev. Father Secchi, S.J.—The author first refers briefly to his former observations of the spectrum exhibited by Uranus, and then mainly states that the spectrum of Neptune consists chiefly of three lines, or bands, placed near the green line, and that its light is entirely devoid of red; this is confirmed by the colour exhibited by the planet when seen through a telescope, which is a sea-green. The same author states that, though the night of the 14th of November last, at Rome, was not very favourable for observation of asteroids, on account of the somewhat cloudy sky, he had been enabled to notice more than 180 asteroids during one hour.

Heat given off by the Moon's Rays.—M. Zantedeschi.—From this paper, which is chiefly a review of what has been done by this and other authors in this direction, we learn that, as far back as the years 1685 and 1781, the Italian *savants*, Geminiano, Montanari, and Paolo Frisi, proved the existence of rays of heat emitted by the moon, by means of lenses and ordinary thermometers. The author refers to his observations made some twenty years ago, when he applied thermo-electric apparatus, as well as spirit thermometers and lenses, and obtained results fully confirming those made and recorded by the Italian *savants* just alluded to.

Colouration of Glass under the Influence of Direct Sunlight.—M. Bontemps.—The author, who is the managing director of the celebrated crystal glass works at Choisy le Roi, states, after referring to the observations on this subject made by the immortal Faraday, in 1824, and MM. Gaffield and Pelouze, in 1863 and 1867, that his observations lead to the following results:—Within three months after having been exposed to sunlight, the best and whitest glass made at St. Gobain is turned very distinctly yellow; extra-white glass (of a peculiar mode of manufacture) has become even more yellow, and gradually assumes a colour known as *pelure d'oignon*; glass containing 5 per cent of litharge was also affected, but far less perceptibly; crystal glass, made with carbonate of potassa (the other varieties referred to contain carbonate of soda), litharge, and silica, was not at all affected; English plate-glass, made by the British Plate-Glass Company, and exhibiting a distinctly azure-blue tinge, remained, also, unaffected. The author attributes this colouration, which begins with yellow and gradually turns to violet, passing through red *pelure d'oignon*, to the oxidising effects of the sun's rays upon the protoxides of iron and manganese contained in glass.

Physical Properties of Arable Soil.—M. Hervé-Mangon.—This paper is divided into the following sections:—Microscopical examination of arable soil; determination of the calorific properties of arable soil; condensation of gas in soils; diffusion of gas through soils; tension of aqueous vapour in soils.

Copper Mines of Lake Superior, and Discovery of Tin in the State of Maine, U.S.—M. Jackson.—In the shape of a letter, written by the author to M. Elie de Beaumont, the author states that, in June last, there was found in the Phœnix copper mine, near Lake Superior, a mass of native copper measuring 65 × 32 × 4 feet, weighing 1000 tons, and valued at 400,000 dollars. In some parts, this mass has, instead of its average 4 ft., 7 ft. thickness. As to the site where the tin ore has been discovered, the author states that he received a sample, sent to him from Winslow by a Mr. Moore, and that, on analysis, he (M. Jackson) found the ore to yield, in its crude state, 46 per cent of pure tin, and after washing, about 75·3 per cent. There exist some forty mineral veins containing the ore, and these veins are workable.

New and Important Works.—M. E. de Beaumont.—In his capacity as one of the perpetual secretaries, the author calls particular attention to two works—viz., that of the illustrious geologist and vice-president of the Belgian Senate, M. Omalius d'Halloy, "On the Human Races, or Elements of Ethnography," which is highly eulogised for its clear and distinct language and simplicity of reasoning; and the work of M. Burmeister, "The History of Creation," which has now reached its seventh edition, and is translated into no less than seven different languages, the original being written in German. The eminent perpetual secretary above named speaks of this work as a most masterly exposition of scientific truths placed before the public in a very attractive and pleasant shape.

Revue Hebdomadaire de Chimie, November 11, 1869.

The number contains the following original matter:—

Powders to which Aniline Colours are Added.—M. Méne.—It appears that there are met with in the trade, a series of powders, of comparatively inert nature, with which aniline colours are incorporated. The author says—These substances are chiefly starch, which has been made to absorb alcoholic solutions of the different aniline dyes, and the coloured powders so obtained are employed in the manufacture of coloured printing-inks. As an improved method of the manufacture of such powders (the author says), I employ the following process:—Dissolve, in ½ a kilo. of 95 per cent alcohol, 10 grms. of copal resin and 1 grm. of magenta red; filter the solution, and incorporate therewith, afterwards, so much dry starch as will form a friable uniformly-coloured mass. The mixture is dried in a properly-constructed drying apparatus, and next ground to powder. When a violet tinge is desired, only half the quantity of magenta-red is applied, and the other half replaced by ultramarine. The addition of copal has the effect of fixing the colouring matter to the starch.

A New Kind of Burette.—M. Gondolo.—This piece of apparatus consists essentially of the graduated tube generally applied; but it is improved upon in the following manner:—The internal conical opening at the bottom is shut by a very carefully-ground-in glass plug of conical shape. To this plug is soldered a glass rod, running through the length of the graduated tube, and passing through a cork at the top; in the cork, a spring has been ingeniously placed, in such a manner as to force the glass rod down, and keeping the plug tightly fitting the opening at the bottom. When it is desired to use the burette, which is, of course, firmly fixed in a proper stand, the hand of the operator lifts the end of the glass rod, which projects outside the cork, for a moment, and, on releasing the action of the hand, the plug is shut again by the action of the spring. Provision is made for the admittance of air, of course; and, according to the author's statement, this kind of burette is now very generally in use in France and Germany, and giving great satisfaction to all who use it.

Detection of Adulterations of Soft Soap.—M. Arbelier.—Soft soap is frequently adulterated by the addition of from 20 to 25 per cent of raw starch, with the view of giving to the soap an appearance which, if genuine, is due to solid stearates formed therein. The microscopic investigation will, of course, readily detect this fraud; but if it is required to apply a chemical test, the author states that 10 grms. of the sample of soap should be taken and dissolved, without the application of heat, in alcohol of 85 per cent; the soap, if unadulterated, will be readily dissolved, leaving no residue. If any residue is left, it can be tested by the well-known methods for starch, as well as for other impurities. Lime is sometimes present.

Trade in Flowers Used for Perfumery.—M. Contet.—From this paper we abstract the following:—In order to obtain, by distillation, 1 kilogramme of the undermentioned essential oils, the annexed quantities of parts of plants are required:—Neroli, 100 kilos. of orange blossom; roses, from 10 to 30,000 kilos. of petals of roses; petitgrain, about 500 kilos. of the leaves of the orange-tree; mint, about 500 kilos. of leaves; lavender, about 250 kilos. of flowers; geranium, about 2000 kilos. of the leaves. The extent of the trade of some of these articles may be inferred from the fact that the neighbourhood of Nice alone produces annually a value of £8000 of one single kind of flower, the well-known sweet-smelling Nizza violet. The leaves of the orange-tree are valued at about 20 francs per 100 kilos. Among the perfumes more generally known in Southern than in Northern Europe belongs the *cassies* (*Acacia farnesiana*), frequently used by both French and Spanish ladies to impart a pleasant perfume to their linen.

November 18, 1869.

Preparation of Gilders' Glue.—M. Totin.—Rabbit skins are cut up to shreds as small as vermicelli, and boiled for some time on a water-bath after previous addition of a sufficient quantity of water. The fluid is separated from the portion of the skin insoluble in water by passing through a sieve; and to the fluid, while yet hot, is next added a solution of 100 grms. of sulphate of zinc and 25 grms. of alum, previously dissolved in pure and boiling water. The mixture is thoroughly stirred up and again filtered through a fine sieve; after this, the clear fluid is poured into a suitable vessel, and left to solidify, which takes place after twenty-four hours in winter and forty-eight in summer. When the solidification is complete, the gelatinous mass is cut up into oblong squares and dried, as is usual with glue. When required for use, the dry glue should be soaked first, for about ten hours, in cold water, and next melted by the aid of a water-bath. 1 kilo. of this dried glue yields a thick solution with from 8 to 10 litres of water.

Preparation of Albumen from Blood.—M. Dolfus-Galline.—The increasing demand for albumen, especially for the use of calico-printing (fixing of pigment and other colours), has at various times led to attempts to obtain a supply of this article from the blood of slaughtered oxen and sheep. The author of this paper describes at great length a process invented by him, and actually in operation on the large scale at the *abattoirs* of Dornach, France. The process is based upon the fact of the coagulation of the so-called cruor of the blood, and its separation from the serum thereof, the latter yielding, by cautious management, a dried albumen which can be applied instead of egg albumen for clear and bright colours, while the former may be manufactured into an albumen suitable for dark pigments. 10 litres of serum yield 1 kilo. of dry colourless albumen, and the blood of two-and-a-half oxen yields just sufficient serum to obtain this quantity of albumen; the blood of ten sheep and seventeen calves also produces the same quantity of dry albumen—viz., 1 kilo.

Gas Aérifuge.—M. Rouillé.—The author describes and elucidates, by a woodcut, an apparatus suitable to manufacture gas from the essence of petroleum. In reality, the gas is simply atmospheric air saturated with the vapour of that essence and conducted through pipes. From experiments which are described in this paper, and which appear to have been fairly and scientifically conducted with impartiality, this mode of gas-lighting is fully 21 per cent cheaper than the use of coal-gas, in Paris, for equal illuminating power. The vapour-gas, however, yields a better light; its illuminating power is far greater, for equal consumption, than that of coal-gas, and the products of its combustion are completely free from sulphur and ammonia. The apparatus are simple and efficient, and may be inspected in operation at No. 211, Rue Lafayette, Paris, where, on every Tuesday and Friday evening, the public are admitted to a room purposely fitted up for photometrical and other experiments.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale, No. 201, September, 1869.

This periodical contains the following papers and communications bearing upon chemical subjects:—

Researches on the Bleaching of Woven Tissues.—M. Kolb.—There exist in the linen fibre, along with cellulose, two distinct substances—one of these is pectic acid, which is readily and very completely eliminated by alkalies; the other is a colouring substance, which is generated during the roating of the flax, giving thereto a greyish hue, and resisting the solvent action of all known solvents, and only separable from the cellulose by dissolving the latter in the ammonio-copper solution. While the quantity of pectinic products amounts in flax to from 15 to 36 per cent, this greyish matter is present therein in infinitesimal small quantity. Chlorine and hypochlorites discolour this substance, but do not dissolve it; perfect bleaching consists, therefore, in two operations—(1) elimination of all yellow colouring matter by means of alkali; (2) oxidation, and hence decolouration, of the greyish matter, which does not, however, as is generally assumed, thereby become soluble in alkalies. The author proposes the use of dilute liquid ammonia as the best so-called antichlorine, and also because it is simultaneously antacid.

Preservation of Butchers' Meat.—M. Gorges.—The process in use on the large scale by the author at Monte-Video is, briefly, as follows:—The meat, in pieces weighing from 2 to 50 kilos., is placed in a mixture of water (85 per cent) the rest being hydrochloric acid, glycerine, and bisulphite of soda. After having been steeped for some time, the pieces are taken out and dusted over with finely-powdered dry bisulphite of soda, and then packed in air-tight boxes filled as full as possible. In this state, the meat keeps fresh any length of time, and becomes perfectly fit for use—equal to fresh butchers' meat—by steeping for a short time in water to which vinegar has been added, and afterwards exposure to air. The author manufactures, at the place above named, an excellent extract of meat, which can be sold in Europe at 6 francs per kilo.; the price of the preserved meat, of which it would be easy to supply to London and Paris daily over 10 tons, is from 50 to 60 centimes per kilo.

Purification of Sewage Water.—M. Durand-Claye.—From this lengthy paper we quote the fact that the mother liquor of the manufacture of sulphate of alumina clarifies and purifies the liquid in question better than any other substance tried by the authors on the large scale. The expense only amounts to 0·0125 franc per cubic metre of fluid (rather more than 35 English cubic feet).

Cosmos, November 20, 1869.

This number contains the following original matter relating to chemistry and allied sciences:—

Analysis of the Meteorite of Deesa.—M. Domeyko.—This meteorite was observed in Chili, near Santiago, and the author, Inspector-General of Mines to the Republic alluded to, gives, in a lengthy paper, the following chemically-interesting particulars:—The metallic portion of the stone has, at 11°, a specific gravity of 7·51, and consists, in 100 parts, of—Iron, 87·17; nickel, 8·75; insoluble silicate, 2·40; phosphuret of iron and nickel, 1·42. The stony part of this meteorite is exceedingly hard, scratches glass readily, and is not scratched by hardened steel, and assumes a brilliant polish. The sp. gr. of this substance is, at 12°, =3·589; it contains 12·62 per cent of nickeliferous iron. 58·45 per cent is soluble, and 41·55 per cent not soluble in HCl. The insoluble portion consists of—Silica, 18·64; magnesia, 17·89; protoxide of iron, 5·71; traces of soda and alumina; nickelliferous iron, 12·62; troilite, sulphide of iron of meteorites, a peculiar protosulphide of iron, 5·01 (we quote the original exactly, but the total adds up to 59·87, as it is given there). The portion soluble in acid consists of—Silica, 20·79; magnesia, 9·70; protoxide of iron, 6·99; lime, 1·45; trace of soda; alumina, 2·27; peroxide of iron, 0·41; with traces of sesquioxide of chromium, phosphorus, and carbon. The insoluble portion approaches the composition of the peridote, and the soluble portion that of pyroxenic minerals.

Lectures at the Conservatoire des Arts et Métiers, Paris.—While the requirements of technical education are often discussed, many of our readers will, perhaps, be interested with the following list:—Geometry applied to arts; descriptive geometry; mechanics applied to arts; civil architecture; applied natural philosophy; applied chemistry; industrial chemistry; the chemistry of dyeing, glass making, and ceramic art; agricultural chemistry; lectures on the theory of agriculture; agricultural engineering; spinning and weaving; political economy and industrial legislation; industrial economy and statistics. Among the lecturers are MM. Becquerel, Peligot, Tresca, Payen, de Luynes, Boussingault, &c.

Mineral Substances applied for Staining Glass and Porcelain.—M. Meunier.—The colours applied to porcelain and glass are in reality coloured glasses, which are burnt into the mass of the white glass or china. As regards the latter, in most cases, after it has been glazed, since most of the substances used as colouring matter do not stand a very strong heat (technically, in French, *grand feu*)—that is to say, the heat at which the porcelain is fired—the burning-in of the colours is effected in muffles. As colouring matters for porcelain are used:—Peroxide of iron for red (brick), brown, violet, yellow, and sepia; oxide of chromium for green; oxide of cobalt and nitrate of protoxide of cobalt and potassa for blue and black; oxide of uranium for orange and black; oxide of manganese for violet, brown, and black; oxide of iridium for deep-toned black; oxide of titanium for yellow; oxide of antimony for yellow; black oxide of copper for green, and red oxide (suboxide) of copper for red; chromate of lead for yellow; chromate of baryta for yellow; chloride of silver for red; chloride of platinum, and chloride of platinum and ammonium, for steel-colour (in fact, metallic platinum); purple of cassius for purple and rose-red colour. Only the following substances stand, without deterioration or volatilisation, the highest heat of the porcelain furnace (they are *couleurs grand feu*):—The oxides of uranium, cobalt, chromium, manganese, iron (peroxide), and titanium. Most of the substances mentioned are not used as such in pure state, but require either to be mixed very intimately, by a previous ignition with various fluxes, or, also, with other substances, to produce the required hue and shade of colour. The chemistry of the colouring matters required by the artists who paint on porcelain is one of the most difficult and intricate portions of the application of that science to art.

Bayerisches Industrie und Gewerbeblatt, September, 1869.

Among the official announcements in this number, we notice the *series lectionum*, or programme of the winter session of the Royal Polytechnic School at Munich, containing the following sections:—

Mathematical sciences; natural sciences; engineering and architectural science; mechanico-technical science; chemico-technical sciences; general class, including modern foreign languages; drawing class.

Police des Mines et Carrières.—An excellent model of the rules and regulations to be observed for the safety of the working of mines and quarries.

Central Air-Heating Stove.—M. Broc.—There is added to this excellent paper a series of drawings. The stove is designed for heating large buildings, as well as private dwellings, keeping up throughout every part thereof a uniform heat at very little expense.

Precautions Required to be taken by those who Work with Mercury.—Dr. Pappenheim.—This paper is the first instalment of a lengthy memoir on the subject of the volatility of mercury, and on tests for its presence in the atmosphere, especially of workshops. It appears that living plants are so highly sensitive to vapours of mercury that they are the best tests for the purpose of detecting even very minute quantities of the vapours of that metal, especially when the plants are young. The effect of mercury upon plants is the decolouration of all the green parts, especially the leaves.

Utilisation of Scraps of Tinned Iron.—M. Bock.—The scraps are placed in a tank made of stout sheet iron. To 1 cwt. of scraps, 6 lbs. of flowers of sulphur, 10 lbs. of caustic soda, and a quantity of water are added, and the mixture brought to ebullition by means of steam, introduced into the tank by means of a suitable pipe. The boiling is continued for about half an hour; the liquor is filtered, evaporated to dryness, and ignited with access of air. The ignited mass is lixiviated with water, yielding stannate of soda and sulphate of soda, which are separated from each other by their different degrees of solubility; both salts crystallise.

Neues Jahrbuch für Pharmacie, von Dr. F. Vorwerk, September, 1869.

This number contains the following original papers and communications:—

Some Little-Known Poisonous Mexican Plants belonging to the Order of Compositæ.—Dr. Huseman.—It appears that the plant known as *Its cuimpatli, Yerba de Puebla, Senecio canicida*, has been submitted to a chemical investigation by the Mexican chemist, De la Loza; he detected a peculiar organic acid, which he called senecic acid. This acid should, according to this chemist, possess poisonous properties; it forms, with potassa and ammonia, deliquescent salts; neither the acid itself, nor its alkaline salts, are precipitated by the soluble salts of lime, magnesia, mercury, silver, copper, and platinum. The acid is soluble in alcohol, and is obtained by treating a decoction of the plant with acetate of lead and removal of the excess of lead by means of dilute sulphuric acid; the fluid so obtained, after filtration, is evaporated to the consistency of a syrup, and left standing for a few days. The acid separates in small, but deliquescent crystals; these are collected and purified by treatment with strong alcohol. The acid and its salts are very poisonous; but the plant and its alcoholic extract are used in Mexico as a powerful febrifuge and anthelmintic.

Contributions to the Search for, and Detection of Blood-Stains.—M. Hirsch.—There is nothing in this paper which is not well-known to all who, in their capacity as forensic chemists, may have to deal with this subject.

Testing Antimony for Arsenic by the Moist Way.—M. Rump.—The author states—During the latter end of last year, on the occasion of the inspection of apothecaries' shops in Prussia, a quantity of tartar emetic was found to contain arsenic; as a consequence thereof, a report was made to head-quarters, at Berlin, and a rigorous inquiry and investigation set on foot by order of Dr. de Mühler, as minister for medical affairs and police (*medizinal polizei*). The methods of testing for arsenic, when mixed up with antimonial preparations, were carefully considered, and the following method of testing, due to the researches of Mine Inspector Strohmeyer, adopted:—2 grms. of the suspected tartar emetic are reduced to a fine powder and dissolved in 4 grms. of pure hydrochloric acid (sp. gr., 1·124). The glass vessel wherein this solution is made ought to be narrow, and capable of being well closed, and of sufficient size to contain an additional quantity of at least 30 grms. more of hydrochloric acid. A quantity of pure hydrochloric acid should be thoroughly saturated with sulphuretted hydrogen gas, and of this acid a quantity of at least 30 grms. is added to the solution of the tartar emetic. The glass vessel containing the solution is well corked, and, after having been shaken up, set aside; the turbidity which at first appears soon subsides (if it does not do so, it is due to the too great saturation of the HCl with HS, and should be remedied by the addition of some pure HCl). If no arsenic is present at all, the liquid remains perfectly colourless; but the slightest trace of arsenic gives rise to a yellow colouration, and very soon after to a perfectly perceptible pure yellow precipitate of sulphuret of arsenic.

Zeitschrift für Chemie von Beilstein, No. 20, 1869.

On Phosphamides.—M. Schiff.—After briefly referring to his former experiments on this subject, and commenting, in a few words, on Dr. Gladstone's treatise on the action of ammonia upon oxychloride of phosphorus, the author says—When perfectly dry ammonia gas is brought into contact with oxychloride of phosphorus, so much heat is at first set free that it is necessary to moderate the action considerably; but it is not possible to eliminate the whole of the chlorine, unless the product first obtained be repeatedly treated with ammonia. The chloride of ammonium can be removed by hot water, since neither that fluid, nor, also, dilute acids, have any decomposing effect upon the triamide thus formed. When phosphotriamide is heated without access of air, it is converted into monophosphamide, NPO, the loss of weight amounting to about 36 per cent. It is clear that only ammonia is disengaged, and no vapours of chloride of ammonium are detected at all, which would certainly make their appearance if a chlorinated amide were dealt with. When phosphoric acid is considered as—

$$P\begin{cases}O.OH\\OH\\OH\end{cases}$$

and the oxychloride of phosphorus as—

$$P\begin{cases}O.Cl\\Cl\\Cl\end{cases}$$

the meaning is that one of the atoms of chlorine has a different chemical function than the two other atoms; and it is just possible that that very one atom is less readily acted upon than the rest. When pentachloride of phosphorus is suffered to act upon aniline, a rather violent reaction takes place; but, with careful management, a whitish-coloured substance, insoluble, and thereby undecomposable in cold water and dilute acids, is obtained; when, however, this substance is boiled with water, it is split up, and phosphate of aniline is among the products of decomposition. The original product is phosphodianilide—

$$N_2\begin{cases}PO\\3C_6H_5\end{cases}$$

and its formation is represented as follows:—1. First action of aniline and pentachloride of phosphorus—

$$PCl_5+3C_6H_7N=N_2\left\{\begin{matrix}PCl_3\\3C_6H_5\end{matrix}\right\}+NH_4Cl+2HCl.$$

2. On being next treated with water—

$$N_2\left\{\begin{matrix}PCl_3\\3C_6H_5\end{matrix}\right\}+H_2O=N_2\left\{\begin{matrix}PO\\3C_6H_5\end{matrix}\right\}+2HCl.$$

Cyantoluylen.—M. Irelan.—The author has investigated the behaviour of chlorotoluol-sulphate of potassa towards cyanide of potassium. When an intimate mixture of these salts is heated, a sublimate is obtained, exhibiting, after re-crystallisation from alcohol, a solid substance forming needle-shaped crystals composed according to the formula—

$$C_9H_6N_2=C_7H_6\begin{cases}CN\\CN\end{cases}$$

On being boiled with a solution of caustic potassa, ammonia is given off, and if, afterwards, sulphuric acid is added, a dicarbon acid (*dicarbonsäure*) is precipitated, which acid is, in all probability, uvitinic acid. Dichlorotoluolsulpho acid yields, when submitted to the same treatment, a cyanised compound.

Behaviour of Epichlorhydrine towards Neutral Sulphate of Potassa and Cyanide of Potassium.—M. Paraschke.—On mixing 1 molecule of epichlorhydrine and 1 molecule of K_2SO_3 in concentrated aqueous solution, and boiling the mixture, a deep yellow-coloured, acrid-smelling fluid was obtained, which solidified on cooling, yielding a crystalline compound, which, after having been repeatedly re-crystallised, yielded a salt, $C_5H_9S_2O_7K_2+2H_2O$; that is to say, disulphoglycerinate of potassa. The reaction of neutral sulphate of potassa upon epichlorhydrin is rather complex, and exhibits two different stages;—

1. $\left.\begin{matrix}CH_2\\CH_2O\\Cl\end{matrix}\right\}C+2\left(\begin{matrix}KO\\KO(SO)\end{matrix}\right)=\left\{\begin{matrix}CH_2K\\CH_2O\end{matrix}\right\}C\left(\begin{matrix}(SO_2)\\(SO_2)\end{matrix}\right)\begin{matrix}OK\\OK\end{matrix}\Big\}+KCl.$

2. $\left.\begin{matrix}CH_2K\\CH_2O\end{matrix}\right\}C\left(\begin{matrix}(SO_2)\\(SO_2)\end{matrix}\right)\begin{matrix}OK\\OK\end{matrix}\Big\}+H_2O=\left\{\begin{matrix}CH_2\\CH_2O\end{matrix}\right\}C\left(\begin{matrix}(SO_2)\\(SO_2)\end{matrix}\right)\begin{matrix}OK\\OK\end{matrix}\Big\}+KOH.$

When 20 grms. of epichlorhydrine were gently heated along with an aqueous solution of cyanide of potassium (15 grms. KCy, and 60 grms. H_2O), a rather violent reaction sets in; but, with proper management, a crystalline compound is obtained, which is readily dissolved by water and alcohol, but sparingly by ether; this substance is composed according to the formula C_4H_5NO.

Identity of Dichlorhydrine obtained from Glycerine and Epichlorhydrine.—The author has compared dichlorhydrine, prepared by passing hydrochloric acid gas into a mixture of four parts of glycerine and three parts of glacial acetic acid, with the dichlorhydrine prepared by passing hydrochloric acid gas into epichlorhydrine. The former boils at from 176° to 177°, and has a sp. gr. of 1·366 at 17·5°; the latter boils at from 175° to 176°, and has, at 17·5°, the very same density as just mentioned. They are both equally soluble in water.

Dicyannaphthaline.—MM. Baltzer and Merz.—When dipotassium-disulphonaphthalate is submitted to distillation with excess of cyanide of potassium, a fluid is obtained which solidifies in the neck of the retort. This crude substance contains two dicyannaphthalines, of different solubility in alcohol. The more readily soluble of the two exhibits, after having been purified, a silky-looking, needle-shaped, crystalline mass, devoid of taste and smell, and fusing at 181°; this substance is completely decomposed at about 200°, and the action of either aqueous solution of caustic potassa or hydrochloric acid yielding, in each instance naphthalin-dicarboxylic acid, a beautifully crystalline compound. The other dicyannaphthaline, far less soluble in alcohol (boiling only), fuses at 260°, is a crystalline compound, and undoubtedly identical with a substance obtained by MM. Darmstädter and Wichelhaus from dinaphthalin-disulpho acid.

Isomeric Cresoles and their Derivatives.—MM. Engelhardt and Latschinoff.—This lengthy memoir opens with an introduction

reviewing the labours of so large a number of scientific chemists who have experimented on this subject, that their names alone would fill a too considerable space. Of the paper itself, we can only give the titles of the headings of its different sections:—Isomeric toluolsulpho acids, $C_7H_7(HSO_3)$; α and β toluolsulpho salts; isomeric cresoles, C_7H_8O; α cresole; α benzoyl-cresole, $C_7H_7O(C_7H_6O)$; α ethyl-cresole; α cresol-sulpho acid; α cresol-sulpho-potassium, $C_7H_6(KSO_3)OH+2H_2O$, and a series of similar salts of various bases; α cresol-disulpho acid; α cresol-disulpho-potassium—

$$C_7H_5(KSO_3)_2OH+3H_2O;$$

β cresole, C_7H_8O; β benzoyl-cresole; β cresol-sulpho acid; γ cresole, C_7H_8O; γ benzoyl-cresole, $C_7H_7O(C_7H_6O)$; γ ethyl-cresole; γ cresol-sulpho acid; isomeric cresotinic acids, $C_8H_8O_3$; isomeric toluylic acids. The memoir is an abstract from a very lengthy paper published in the Russian language, and is so full of formulæ and references to different papers published on this subject that it is not possible to enter into more details here.

Some of the Products of Decomposition of Trichloromethylsulphurous Acid.—M. Loew.—When trichloromethylsulphobromide is submitted, in alcoholic solution, to a temperature of about 110°, while enclosed in a sealed tube, and the contents of the tube are next diluted with water, a heavy oil is separated, while the supernatant liquid contains free sulphurous acid; this reaction takes place according to the following equation:—

$$\underbrace{(CCl_3)[SO_2]Br}_{\text{Trichloromethyl-sulphonbromide.}} = \underbrace{CCl_3Br+SO_2}_{\text{Carbontrichloro-bromide.}}.$$

Along with the sulphurous acid, a small quantity of trichloromethylsulphonic acid is detected. Carbontrichlorobromide boils at 98°, and is, when passed through a dull red-hot combustion tube, decomposed into bromine and solid chloride of carbon. The author did not succeed in obtaining the analogous iodide; neither did he obtain a trichloromethyl-sulpho urea. While attempting to prepare dichloromethylen-sulphon, by submitting trichloromethylsulphinate of sodium to destructive distillation, according to the formula—

$$(CCl_3)[SO]ONa=NaCl+(CCl_3)[SO_2],$$

a very small quantity of that substance was obtained; but the reaction went further, and other substances, among which, perchloride of ethylen, were obtained, this reaction being represented by—

$$2((CCl_3)[SO_2])=2SO_2+C_2Cl_4.$$

Action of Direct Sunlight upon Iodide of Potassium.—M. Loew.—A solution of iodide of potassium is, even when kept in well-closed bottles, slowly decomposed by the action of daylight, and assumes a somewhat yellowish tinge, due to free iodine. The author filled a number of glass tubes for about from one-half to three-fourths of their capacity, with a solution of iodide of potassium, and, after having sealed these tubes, exposed them to direct sunlight. Another set of tubes were likewise filled with the same solution, but all air was expelled, and the tubes sealed during and after the solution had been boiling for a considerable time. These tubes were also exposed to the action of direct sunlight; after three and four months' exposure, the tubes and contents were examined; those wherein no air at all was left were found to be perfectly colourless, no decomposition of the contents having taken place. As regards the other tubes, the following results are noticed:—(1) Under the influence of light, the oxygen of the air decomposes iodide of potassium, iodine in small quantity is set free, while hydrate of potassa is found in the liquid. (2) This decomposition is limited, and does not, even when a large quantity of oxygen is present, increase, because a portion of the iodine set free enters again into combination with the caustic potassa set free, forming iodide of potassium and iodate of potassa. (3) The testing for ozone by means of a solution of iodide of potassium and starch (or paper prepared therewith) is of no value whatever, unless care has been taken to exclude direct sunlight.

Precipitation of Cobalt by Sulphuretted Hydrogen, and Purification of Salts of Manganese containing Cobalt.—M. Muck.—The gist of this paper is that boiling-hot solutions of cobalt are, even when free acid is present, readily precipitated by sulphuretted hydrogen. When there is added to such a solution carbonate of manganese, in sufficient quantity, the sulphide of cobalt is completely precipitated, and, after elimination of the free HS, a pure solution of manganese is obtained. The author also states that there occur many ores of manganese which contain large quantities of cobalt ore.

Phenol from Oxybenzoic Acid.—M. Rosenthal.—The author has prepared phenol by distilling oxybenzoic acid with lime; and, on investigation, found it to be in all respects identical with the phenols obtained from tar, salicylic acid, and paraoxybenzoic acid.

Ethyloxybenzoic Acid.—M. Rosenthal.—The author says—I tried to prepare, from oxybenzoic acid, an acid of the formula—

$$C_6H_3\begin{cases}OH\\COOH\\COOH\end{cases}$$

by causing carbonic acid and sodium to act upon the compound—

$$C_6H_4\begin{cases}OH\\COOC_4H_5.\end{cases}$$

Instead of obtaining the desired result, the author obtained the compound—

$$C_6H_4\begin{cases}OC_2H_5\\COOH\end{cases}$$

which is undoubtedly due to the conversion of Na and C_2H_5; this substance is ethyloxybenzoic acid, and was, on comparison, found to be in every respect identical with the compound obtained by heating oxybenzoic acid with KHO and C_2H_5I.

Les Mondes, November 18, 1869.

Refined Resin Oil.—M. Curie.—When resin is submitted to destructive distillation, it yields various oils of different specific gravity, acetic and phenic acids, water, tar, and gases; the crude oil is often applied for the making of printing-ink, as well as waggon grease. The author treats the crude oils, tar inclusive, with lime, and, by fractioned distillation between 140° and 260°, obtains what is known as essence of resin. At 370°, an oil is obtained which, for lubricating purposes, is nearly as good as best olive oil, and is an excellent substitute for turpe in oil-paints. This oil is sold at Bordeaux at 50 francs (£2) per 100 kilos.

Treatment of the Sewage of the City of Rheims.—MM. Houzeau, Devédeix, and Holden.—In a lengthy paper, the authors detail the results of a series of experiments made on a sufficiently large scale to form a proper opinion as to the value and permanent applicability. The processes which have been applied are:—(1) Treatment with sulphate of iron and lime; (2) treatment with lignite and lime; (3) treatment with small coal (dust, rather) and a small quantity of sulphate of iron and lime. The two first processes yield a manure; the last a fuel. The city of Rheims is situated on and near the banks of the Vesle, and contains, exclusive of the large garrison, a population of about 61,000 inhabitants. According to a report of M. Marisdort, Professor of Chemistry at this place, the process, by means of the use of lignite, is a complete success.

NOTES AND QUERIES.

Reducing the Metal from Impure Chloride of Zinc.—Can any of your readers inform me of a practical and profitable method of reducing the metal from impure chloride of zinc?—AN OLD SUBSCRIBER.

Aluminium Sulphide and Phosphide.—(Reply to "D. H.")—See Berzelius's "Traité de Chimie," vol. ii., p. 157 (Paris, 1846), and "Handbook of Chemistry," by Gmelin, vol. iii., pp. 309 and 311. Both works may be inspected at the Library of the Commissioners of Patents.

Atomicity of Aluminium.—(Reply to "Dubitans.")—Aluminium is tetratomic and pseudo-triatomic, like carbon. In the simplest formulæ of aluminium compounds, the metal is represented as triatomic, as, for example, $Al^{iv}Cl_3$ $Al^{iv}K'2SO_4+12H_2O$; but the specific gravity of the vapour of aluminium chloride shows that the true formula is Al_2Cl_6, and not $AlCl_3$. Hence it is probable that each aluminium atom is really tetratomic, the constitution of the chloride being—

$$\begin{array}{l}Al^{iv}\!=\!Cl_2\\|\\Al^{iv}\!-\!Cl_2\end{array}$$

—ATOMICITY.

Gas and Oil Furnaces.—No one seems inclined to give me the information as to getting up white heats in a small furnace with ordinary gas from the mains, from which I infer no one of the readers of the CHEMICAL NEWS has done it, nor sees his way how to do it. As I find, on inquiry at the gas office here (Runcorn), that they will not allow any reduction in price for use in such quantity, save some 2½ discount, I must try oil of some sort or other. Which is best for my purpose? I want to have as *clean* a heat as possible—that is, free from sulphur and deposit of any kind that would interfere with the action of the vapours I introduced on the clay goods in the kiln. At first thought, you would fancy a flame from oil should not leave any deposit; but I am not so sure, as the gas from a gas producer of Siemens's covered the goods with brown-red dust.—J. C.

MEETINGS FOR THE WEEK.

MONDAY, Dec. 6th.—Royal Institution, 2. General Monthly Meeting.

VOL. XX. No. 524.

ON THE

CONSTITUTION OF SODIC SULPHATE IN SOLUTION.

By CHARLES TOMLINSON, F.R.S.

II. LÖWEL'S HYPOTHESIS—ANOTHER HYPOTHESIS.

As there is no harder or pleasanter intellectual work than original research, so there is no harder or more unpleasant moral work than having to modify or re-construct one's own theory after having spent years of toil in establishing it, and even after it has been accepted with applause by competent critics. This is what M. Löwel has done; and I cannot sufficiently honour and respect him for his candour in having been the first to awake to the sense of his own defects, and to wind up his work by saying so.

As already stated, his first five memoirs were published between 1850 and 1855. In his sixth and last memoir, published in 1857, he is led, chiefly by three considerations, to suppose that, between the boiling point of a saturated solution of sodic sulphate (103·17° C.) and the point when the 7-atom salt begins to be deposited (18°), it is not this modified salt, but the anhydrous variety, that is held in solution. His reasons are the following:—

1. That the 10-atom salt parts so readily with its water of crystallisation by mere exposure to the air at temperatures between 15° and 20° C.

2. That Faraday found, on evaporating a solution of the 10-atom salt below 100° C. (or, according to Mitscherlich, below 40°), the anhydrous salt was deposited.

3. That, in boiling for some time a saturated solution of the 10-atom salt, small, hard, granular crystals of the anhydrous salt are formed as the solution becomes concentrated.

But M. Löwel cannot get rid altogether of his molecular theory. Although he admits that, between the boiling point of a saturated solution (103·17° C.) and the point when the modified salt begins to be formed (18°), the anhydrous salt is held in solution, yet, at and below 18°, a molecular change comes over the solution, by virtue of which it holds or begins to deposit the 7-atom salt.

In weaker solutions, it is admitted that this molecular change takes place at yet lower temperatures. A boiling solution of 2 parts of the 10-atom salt to 1 part of water, for example, must be cooled to 7° or 8° C. before it deposits the modified salt; while a solution of 1 part salt to 1 part of water must be reduced to 0° before the 7-atom salt is deposited. Hence the 7-atom salt is not deposited at the same temperature, but at very different temperatures, low in proportion as there are fewer saline molecules in solution. He admits that it was an error to suppose the 7-atom salt to be already formed, since such solutions do not begin to deposit the modified salt as soon as the temperature passes below the point at which the solutions would be saturated with that salt if it were really present. Thus the boiling saturated solution would be saturated with the 7-atom salt at about 26° C., and it did not begin to deposit that salt under 17° or 18°. The weaker solution (2 salt to 1 water) would, in like manner, be saturated at 18°; but it was reduced to 8° before the 7-atom salt appeared; while the still weaker solution (1 salt to 1 water) required a reduction of temperature equal to 0°. The first solution evidently contained anhydrous salt up to the very moment when it began to deposit the 7-atom salt; and there is no reason to suppose the other two solutions, although much less rich in salt, to have been differently constituted. Moreover, when the second solution has deposited the 7-atom salt at 7° or 8°, so long as it remains in contact with these crystals, it possesses fixed points or terms of saturation, limited by the temperature—that is, it deposits the 7-atom salt when its temperature is reduced, and it re-dissolves it to saturation when the temperature rises; but, if this elevation of temperature reach to 22° or 24°, so that the 7-atom salt is totally dissolved, the solution will not deposit crystals when the temperature again falls a little below 18°, but it must be lowered to 8° or 7°, just as if it had not deposited salt at all. "Hence," he says, "I conclude that the 10-atom salt, as well as the 7-atom salt, in passing into solution, at whatever temperature, gives up the whole of its water of crystallisation. Under what conditions, then, are these salts in solution? I can only give hypotheses; and, without seeking to define this condition, it may be best to say that, in passing into solution, they assume an indeterminate molecular constitution, which may be termed the molecular constitution of sulphate of soda in solution, which differs from the molecular constitution of the crystals of the 10-atom, the 7-atom, and the anhydrous salt."

Löwel has given very full tables of the solubility of each of the three forms of sodic sulphate at various temperatures, and his determinations extend to two places of decimals. "I could not," he says, "determine the point of maximum solubility of the anhydrous salt at temperatures below which it begins to deposit the 7-atom salt. At 18°, the change of state is made suddenly; the solutions become troubled, and deposit crystals of the 7-atom salt in a pulverulent form."

Here I venture to think M. Löwel missed his opportunity. If, instead of depositing "crystals of the 7-atom salt," he could have written, "the anhydrous salt," he would have saved himself from much embarrassment, and the present discussion would have been unnecessary.

It was in repeating some of M. Löwel's experiments during the cold weather of December, 1867, that I observed the sudden troubling of the solution. A stream of nearly ice-cold water was allowed to run upon a flask containing a warm supersaturated solution of sodic sulphate, when it suddenly became opaque, from the formation of a multitude of minute crystals, which seemed to increase in number on gently shaking the flask. On repeating the experiment with more care with solutions in test-tubes placed in transparent freezing mixtures, these crystals were soon recognised as the octohedra of the anhydrous salt. I will quote from my note-book a few out of many of the experiments that were made to determine what seemed to me to be a very important point; for it was this experiment that first led me to question the integrity of the molecular theory, as well as the reality of the so-called catalytic action of the sides of the flasks and of solid nuclei.

A solution of 3 parts of the 10-atom salt to 1 part of distilled water was boiled at 218° F., when a small portion of anhydrous salt was thrown down. The solution was filtered into a flask, in which it was again boiled. The flask was then plugged, with a thermometer passing through the plug. When the solution had cooled down to the temperature of the room, the flask was put into cold water. At 54°, a few well-shaped, sharply-cut, octohedra began to fall. At 50°, the number of crystals had so greatly increased as to render the solution opaque; heat currents were liberated, and the temperature rose to 58°.

Two parts of the 10-atom salt to 1 part water: octohedral crystals began to form at 48°.

One part salt to 1 of water: at 35°, a few well-shaped octohedral crystals were thrown down.

So far, then, it seemed to me to be perfectly well made out that the 10-atom salt, in passing into solution, gives up the whole of its water of crystallisation to the solvent. In heating the solutions, a dendritic crystallisation of the anhydrous salt creeps up the side of the flask just above the level of the solution; and, in filtering strong solutions,

a thin anhydrous crust forms on the surface of the liquid in the filter. The proofs are manifold that the anhydrous salt is in solution; but the most convincing proof of the fact seems to me to be the throwing down of anhydrous crystals on lowering the temperature of the solutions to a sufficient degree.

The abrupt change that takes place in the curve of solubility of the 10-atom salt at 33° or 34° C. was pointed out by Gay Lussac, and explained by him that, whereas it is the saline molecule $NaO,SO_3+10Aq.$ that enters into solution, yet, beyond this point, when the solubility diminishes up to boiling, it is the anhydrous salt that is in solution.

Löwel remarks on this:—"We can easily explain why the solubility of sulphate of soda presents this curious anomaly of increasing with the temperature up to a certain maximum, and then diminishing as the temperature rises. So long as the salt is in the form of 10-atom crystals, its solubility increases from 0° to 34° C. Above 34°, this salt no longer exists; it becomes anhydrous, with a different molecular constitution and solubility. The solubility of the anhydrous salt follows an inverse order as compared with that of the 10-atom hydrate. It diminishes in proportion as the temperature rises, or, what is the same thing, it increases as the temperature falls from 103·17° (the boiling point of a saturated solution), not only to 34°, but also to 18° and 17°, when the dissolved salt undergoes a new modification in its molecular constitution, and begins to form crystals of the 7-atom hydrate."

Now, if it be true that the 10-atom hydrate remains in solution up to 34° C. (93·2 F.), solutions made below that temperature ought to deposit the 10-atom salt on cooling in close vessels, just as they do in open vessels where they are in contact with nuclei; but the fact is, such solutions still deposit the anhydrous salt. Solutions saturated at about 85°, or from that to 88° F., and filtered into flasks warmed to that point, and then plugged, were kept until the next day, without any deposit of salt. On detaining them for some time in a freezing mixture, at from 16° to 25° F., they sometimes froze, but, on several occasions, they threw down small, well-defined crystals of the anhydrous salt. Hence, it cannot be true that, up to 34° C., it is the 10-atom salt that is held in solution.

There remains still one point to be discussed. M. Löwel supposes that the supersaturated solutions, in cooling to 18° or 17° C. (64·4 to 62·6 F.), assume the molecular constitution of the 7-atom hydrate; and, further, that, when this salt is deposited, the non-crystallised portion of the solution is the mother liquor of the 7-atom salt. He determines the solubility of this 7-atom hydrate by carefully withdrawing, by means of a warm pipette, a little of the so-called mother liquor at a known temperature, weighing it, evaporating it to dryness, and so calculating the solubility of the 7-atom salt in terms of the anhydrous salt obtained by the evaporation.

But, suppose the so-called mother liquor resting on crystals of the 7-atom salt is once more a solution of the anhydrous salt, what then becomes of the table of solubilities? and what of the theory of molecular change at 17° or 18° C.?

I made a solution of about 2½ parts of the 10-atom hydrate in one part of water; boiled it, and filtered it into three test-tubes, which were then plugged with cotton-wool, and placed upright in a rack close to the window to cool. They were then put into water at from 35° to 40° F., when octohedral crystals of the anhydrous salt were deposited in all three solutions. The tubes were now returned to the rack, when, in a few hours, the 7-atom salt was formed, a few prisms with oblique summits being well marked. The tubes were now put into a freezing mixture, at 20° F., when another shower of beautiful octohedra took place. I need hardly say that, if the molecular change insisted on by M. Löwel had taken place, and if the solution resting on the 7-atom hydrate had been its mother liquor, crystals of the 7-atom hydrate must have been thrown down, and not those of the anhydrous salt.

The tubes were again returned to the rack; when, after some time, another formation of the 7-atom hydrate took place. Next day, in order to be quite sure that it was the 7-atom salt at the bottom of the tubes, the cotton-wool plug was removed from one of them, when crystallisation of the 10-atom salt at once set in from the surface, and, proceeding downwards, converted the deposit into an opaque, chalky mass, or, as Ziz says, "like boiled white of egg," the crystallisation above it being translucent, like ground glass. The two remaining tubes were put into a freezing mixture at about 10° F. The crystals were long in coming, but at length a few well-defined octohedra fell down from the solution in each tube.

I remember that Professor Daniell, of King's College, was in the habit of introducing the same experiment, under different forms, even to variations in the shape of a bottle or flask, in order that his pupils might be allured by the principle involved, rather than by the form of the apparatus. Profiting by this useful example, I prepared a solution of about 4 salt to 1 water, in flasks, where, with much less depth, there was a greater body of solution than in the tubes. The flasks were exposed to the cold of the window-ledge, where they remained all night. Next morning, there was a copious deposit of the 7-atom salt. On putting one of the flasks into a freezing mixture, at 25° F., there was an abundant liberation of anhydrous crystals from the so-called mother liquor of the 7-atom salt, but which is really a solution of the anhydrous salt.

I ought, perhaps, to apologise for drawing thus freely on my note-books for these experiments. My best excuse is that they have not been previously published. In my memoir on "Supersaturated Saline Solutions," I was satisfied with the statement, accompanied by one experiment only, that solutions of Glauber's salt, when removed from the influence of nuclei, hold anhydrous salt in solution, and deposit it on a proper reduction of temperature. Such was my conclusion two years ago; and I see no reason to alter my opinion now. On the contrary, that opinion is strengthened by experience, and by recurring to Professor Daniell's favourite process of varying and multiplying the means, so as to become more secure of the end. One such variation I cannot help giving, since it leads to the same conclusion, by means of a physical test of great practical value.

In the experiments for determining the elasticity of steam from pure water, the elasticity is diminished for any given temperature, if a small portion of a salt, soluble in water and not capable of rising in vapour with it, be allowed to ascend to the top of the mercurial column, the column rises, thereby indicating a diminished elasticity of the steam. The adhesion of the soda to the water tends to restrain the water from evaporating, and this tendency is a measurable force, and here measured; for it partly balances the tension of the water, or its tendency to emit steam, and thus makes the steam-emitting tension of a solution of soda measurably less than that of pure water at the same temperature.

Now, it is clear that, if, instead of soda, Glauber's salt be used in experiments of this kind, there would be a smaller amount of diminution in the elasticity of the steam if the salt in solution retained its water of crystallisation than if it entered into solution in the anhydrous form. In a valuable series of experiments by Wüllner,* it appears to have been established that, for solutions of various strengths (such as 10, 20, 30, &c., per cent of Glauber's salt in pure water), and at various temperatures, from 10° to 100° C., the diminution in the elasticity of the steam is proportional to the quantity of *dry* salt in solution; and, further, that, at the point of maximum solubility of this salt, no molecular change takes place, or it would have impressed itself on the curve which represents the elasticity of the steam. The general conclusion for the salts tried is that the action of efflorescent salts is

* *Pogg. Ann.*, ciii., 529, and cx., 564.

expressed in terms of the dry salt, while, for deliquescent salts, it is in terms of the hydrated salt.

I cannot wind up without entering a protest against the doctrine involved in the foot-note to M. Dubrunfaut's paper (CHEMICAL NEWS, vol. xx., p. 241), which amounts to this—that, if a man repeat the published experiments of others without knowing it, he is entitled to claim the results as original discoveries of his own. I am quite aware that credit is given to M. Löwel in our text-books for discoveries that belong to previous inquirers; and, with all due respect for him, I cannot help thinking that he would have improved his work by quoting his authorities more freely. Now, at the time when Löwel commenced his labours, a large number of well-attested facts had been established by such men as Ziz, Ogden, Faraday, Turner, Graham, and others. Löwel does refer incidentally to Ziz and Faraday, proving that he knew something of their results; and yet we are now coolly told that all those honoured names are to be swept away, and Löwel only referred to as the discoverer of the leading phenomena of supersaturation. If such reasoning and practice were applied in literature as they are on some occasions in science and the useful arts, we should realise the condition of the modern epic poet, who declared that he had splendid thoughts, only those scoundrels, the Ancients, had already appropriated them.

Highgate, N., November 24th, 1869.

ON SOME

TECHNICAL APPLICATIONS OF THE SPECTRUM MICROSCOPE.*

By H. C. SORBY, F.R.S., &c.

MY object in publishing the following paper is to show that the spectrum microscope may be applied with advantage in several departments of technical inquiry, and more especially to describe the methods useful in such investigations. Since these will be much more readily understood by means of practical illustrations, I shall not make many general introductory remarks, but reserve an account of each particular process until I come to those practical questions which require its adoption.

In the first place, I beg to refer to my papers "On a Definite Method of Qualitative Analysis of Animal and Vegetable Colouring Matters,"† and "On the Colouring Matters of Blue Decayed Wood,"‡ since much that I shall describe will be a continuation and application of what they contain. I shall make use of the same scale for measuring the position of the absorption bands, and the same notation and symbols to express the varying power of absorption in different parts. This scale is an interference spectrum with dark bands, which divide the whole visible spectrum into twelve portions of equal optical value; and it is so adjusted that the sodium line, D, is situated exactly at $3\frac{1}{2}$. On this scale the principal Fraunhofer lines occur as follows:—

A .. $\frac{2}{3}$	B .. $1\frac{1}{2}$	C .. $2\frac{5}{8}$	D .. $3\frac{1}{2}$
E .. $5\frac{11}{16}$	*b* .. $6\frac{5}{16}$	F .. $7\frac{1}{2}$	G .. $10\frac{1}{2}$

The only objection to this scale is that its accuracy is dependent on the careful preparation of the plate of quartz. I have myself made several perfectly alike and accurate, and nothing but proper care is required. When once accurately made, no scale could be more convenient, since the bands occur at equal optical intervals over the whole spectrum, and are quite distinct when the slit is opened rather wide, which is sometimes a great advantage. In these two respects it is far superior to any other scale hitherto proposed.

The intensity of absorption will be expressed by means of dots, hyphens, and dashes; thus:—

Not at all shaded		Blank space.
Very slightly shaded	.	Single dot.
Slightly shaded	..	Double dots.
Moderately dark	– –	Double hyphens.
Very dark	—	Single dash.

When these symbols are printed *between* numbers they signify that there is a more or less strong absorption between those points of the spectrum as measured by the above-named scale; whereas when they are printed *under* numbers they signify that there is a distinct absorption band, of the intensity expressed by the different symbols, the *centre* of which is situated at that point of the scale indicated by the figures. This latter method is extremely simple and convenient, and often serves to express all that is requisite. It may, perhaps, appear imperfect to those accustomed to the study of the spectra of substances in the state of incandescence, but it is in all respects well adapted for the study of the spectra of solutions, in which a slight difference in the character of the solvent often makes far more difference in the position of the bands than any that could result from errors due to the employment of such a scale and notation. To hold the liquids under examination, I in most cases employ narrow, deep cells, usually one-eighth of an inch diameter, and half an inch deep, so mounted that they can be examined either in the line of the length or at the side; but occasionally I use rather wider, as much as two and a half inches long.

By using these narrow cells very much less material is required for successful examination, which is not only most important when very little is at command, but even in other cases often effects a considerable saving of time in filtration and evaporation.

I shall divide my subject into three principal heads, viz., 1. Various facts connected with wine; 2. Those relating to malt liquors; and—3. Such as illustrate the methods that may be employed to detect adulteration in various substances used as food or medicine.

1. *On the Colouring Matters of Wines.*

The pure colour of fresh dark grapes is best prepared by removing the skins, heating them in alcohol, evaporating the solution to dryness, re-dissolving it in a little water, filtering, and again evaporating to dryness in a small saucer, in which the colour may be kept as a stiff syrup for many months without material change. It belongs to the group of colours which I called group B in my paper in the *Proceedings of the Royal Society*—that is to say, sulphite of soda produces no immediate effect when added to a solution rendered alkaline by ammonia; but when added to one made acid with citric acid, it almost immediately removes the detached absorption in the green, so that the solution becomes very pale.

Since this colour of dark grapes is purple when dry and quite neutral, it may be called *Vitis purple*. I have not yet met with it in any other fruit, unless it be in that of the common crowberry (*Empetrum nigrum*). One of its peculiarities is that it easily passes into insoluble modifications. It belongs to my sub-group B al_o am_o, since it does not give any decided narrow absorption band in an alcoholic solution, when either neutral or with excess of ammonia. Such colours are amongst the most difficult to distinguish from one another, and I have not yet been able to discover any more satisfactory method than the following:—A slight excess of ammonia should be added to the alcoholic solution; made so dilute that the absorption in the orange part of the spectrum is distinct, but yet very far from black, and the position of the limit of the absorption towards the red end carefully measured and recorded, thus—$1\frac{1}{2}$ . . . .

The same limit should also be ascertained after con-

---

* Communicated by the author, having been published in the *Quarterly Journal of Microscopical Science*, vol. ix., new series, p. 358.

‡ *Quarterly Journal of Microscopical Science*, January, 1869.

siderable excess of hydrochloric acid has been added to the solution, both in water and in alcohol; which solutions sometimes give the same, but sometimes materially different, spectra. These various limits of absorption vary with the depth of colour, but by taking care to have solutions which give equally strong absorptions, and comparing them side by side, it is often very easy to distinguish from one another very closely allied colours—for example, that of dark gooseberries from that of grapes, or that of fresh grapes from that of new dark wines. The difference between these latter is proved, not only by the spectra, but also by other facts.

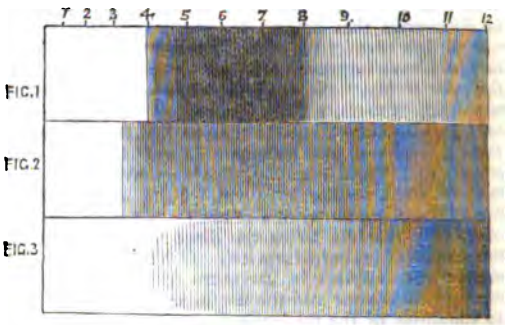
In my paper in the *Proceedings of the Royal Society* already cited (p. 443), I showed that when certain colouring matters are dissolved in water or alcohol, they give deep-coloured solutions, which rapidly fade to nearly colourless; but when these faded solutions are evaporated to dryness, the colour is completely restored to its original state, and is also made quite as dark as if it had never faded, by adding some strong acid; so that the fading is not due to decomposition, but to a molecular change rapidly taking place in dilute solutions. The colour of fresh grapes is an example of this; and by comparing with a standard which did not fade, the solution immediately after the colour was dissolved, and the same after less than an hour, when no further change occurred by keeping it longer, I found that the faded required fully five times the thickness to give the same intensity of absorption at the yellow end of the green. On the contrary, new dark wines evaporated to dryness do not fade at all in such a manner when re-dissolved in water.

This colour of new wines appears to be produced at a very early part of their formation. By dissolving the colour of the fresh grapes in the juice, adding a little yeast, and keeping the solution warm for a few days, the colour appeared to be changed into that found in new wines, and did not fade at all when re-dissolved in water. The colour kept as dry syrup for three years showed a similar change. I think it must be, therefore, due either to fermentation or to a slight oxidisation. I am much inclined to adopt the latter explanation, for if citric acid be added to an aqueous solution of the fresh colour, and then a small quantity of hypochlorite of soda, the colour is changed from pink to pink-red, the absorption is found to extend more towards the red end, and to be more uniform over the green and blue; in all which particulars it corresponds with the spectrum of new wine. No such change occurs when the wine is treated in the same manner, as though this alteration had already taken place. Both these colours belong to my group B; but when either is still further oxidised by means of rather more hypochlorite of soda, a sort of orange colour is produced, which seems to correspond with that of port wine kept for twenty years or more in the cask; and when still further changed, it becomes quite pale, like very old wines. The following table will show these facts more clearly:

Colour of dark grapes in citric acid and water	..	..	..	4	..	4½	—	—	18½	.. 11 — —
Ditto, after adding a little hypochlorite of soda	..	..	..	3½	..	3¾	—	—	—	—
New natural port wine	..	..	..	3¼	..	3¾	—	—	—	—
Ditto, after adding a little hypochlorate of soda	..	..	..	3¼	..	3¾	—	—	—	—
Colour of dark grapes with more hypochlorite of soda	..	..	..	5	..	6	—	—	10	—
New natural port wine with ditto	..	..	..	5	..	6	—	—	10	—
1834 port from the cask	..	..	..	5	..	6	—	—	10	—

Since this change in the spectrum depending on the state of oxidisation is of considerable interest as illustrating a general law, I here subjoin a woodcut,* in order to render more intelligible to those not accustomed to the use of the symbols employed in the above table. Fig. 1 shows the spectrum of the colour of dark grapes in its natural state, in citric acid and water. Fig. 2 is the spectrum of the oxidised modifications met with in new wines; and Fig. 3 that of the per-oxidised colour found in very old wines, or formed by the more complete artificial oxidisation of the other two.

This colour of very old wine belongs to my group C, and is not changed by adding sulphite of soda to an acid solution; whereas, as already mentioned, the characteristic colour of very new wine belongs to my group B, and if it could be obtained in a pure state, would probably become nearly colourless on the addition of the sulphite. This



difference between the colour of new and old wine has enabled me to contrive a method by means of which I can ascertain the approximate age of port wine kept in the cask. In these experiments I have been very much assisted by my friends, Mr. Joseph Prestwich, F.R.S., and Mr. Alexander Hay, of Sheffield, who have most kindly supplied me with the requisite samples.

(To be continued.)

* We are indebted to Messrs. Churchill and Sons for the use of this woodcut.

NOTE ON THE AMERICAN ECLIPSE.

Dr. Morton, Professor of Chemistry in the University of Pennsylvania, has kindly forwarded me photographs of the phenomena of totality. By combining in the stereoscope pairs of these, separated by intervals of about half a minute of time, the black globe of the moon appears projected far in front of the luminous prominences and the corona, which are, therefore, clearly seen to belong to the sun. Glass transparencies from negatives specially selected for this purpose, and appropriately mounted, would show these phenomena in a very striking manner.

William Crookes.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, December 2nd, 1869.

Dr. A. W. Williamson, F.R.S., &c., President, in the Chair.

The minutes of the previous meeting having been read and confirmed, the following certificates were read:—

For the first time—James Bell, Howell Hill, Ewell; G. R. Hislop, Gas Works, Paisley; William Ladd, Beak Street, Regent Street; Alfred Bird, Worcester Street, Birmingham; H. Seward, 15, Barnsbury Park, N.; Edwin Lepper, 11, Maiden Lane, Queen Street, Cheapside, E.C.

For the second time—Samuel Jefferson, Secretary to the Yorkshire Board of Education, Woodville Terrace, Woodhouse Lane, Leeds; Clements Higgins, Demonstrator of Chemistry, King's College, London; James John Bourey, Analytical Chemist, 10, Stepney Causeway, E.

For the third time—Matthew H. Cochrane, 108, Paul Terrace, Glasgow; Edward Smith, Practical and Pharma-

ceutical Chemist, Strand, Torquay; Thomas Walton, M.R.C.S., and L.S.A., Lecturer on Chemistry at the Hull and East Riding School of Medicine, Kingston-upon-Hull; G. Manley Hopwood, 22, Grosvenor Square, All Saints, Manchester; John Wiggin, Pharmaceutical and Analytical Chemist, Ipswich; Thomas Gibb, A.R.S.M., Engineer; George Harrison, Analytical Chemist, 26, Havelock Square, Sheffield; Sir Roderick Impey Murchison, Bart., F.R.S., Belgrave Square.

The last-named gentlemen were ballotted for and duly elected.

The first paper read was entitled "*Remarks on some Points in the Nomenclature of Salts*," by H. G. MADAN, F.C.S.

The author calls attention to the unsettled state of chemical nomenclature, and the difficulty of teaching the science while hardly two of our text-books adopt the same system of names, and while specimens of so many totally different systems are to be found in our periodicals. He then refers to the terminations to the electro-negative radicles, such as *-ide*, *-ite*, and *-ate*, and suggests that the accepted principle of indicating the amount of oxygen in the radicle by a change of a vowel in the name might be extended, so as to embrace such substances as chlorine and sulphur, which form, with oxygen, more than two radicles.

To distinguish the several members of each group of salts containing the same electro-negative or electro-positive radicle, the author prefers rather to add a prefix, such as *proto-*, *di-*, *tri-*, *per-*, &c., to the existing generic name for the salts of the electro-negative radicle with which it is associated than to change the termination of the name of the electro-positive radicle into *-ic* or *-ous*, as the prefix requires the least alteration in existing names, and is the more elastic system of the two.

Mr. Madan does not see the advantage of calling radicles by their Latin names, such as *argentic* nitrate or *ferrous* chloride, but if such a system is considered convenient, it should be carried out consistently, by using such terms as *kalic*, *natric*, *stilbic*, *hydrargic*, &c. The system of terminology proposed by Mr. Harcourt,* and adopted by Roscoe and Watts is, in the opinion of the author, more simple, permanent, and yet elastic, than any other.

Professor ATTFIELD thought the chief point about a name should be that it was unalterable. He objected to the use of vowels or of Latin or Greek numerals to express the name of a salt, as their views of the constitution of a substance sometimes changed, and when such was the case, it became necessary to alter the name.

The PRESIDENT said that Mr. Madan's proposal to revert to the use of such terms as *proto-*, *sesqui-*, and *per-* in order to designate the place of bodies which differ in their quantity of oxygen and chlorine in a series, implied that the series was known, whereas we are constantly altering our knowledge of such series. These words had been productive of considerable inconvenience and confusion, and he thought the terminations *-ous* and *-ic* as used by most writers, including Mr. Roscoe and Mr. Watts, were far more convenient. These terminations only denote a kind of difference in the constitution of certain substances: such a difference might be ascertained as a matter of fact. They might find other terms of each series, and a body which was first might become second, but if it contained less oxygen than another, it was correctly distinguished by the termination *-ous* instead of *-ic*. Mr. Madan seemed to think it necessary always to retain Latin words if they were used in certain cases. It was held by some persons that a variety of name was in many cases desirable amongst such compounds as Prussian blue, where iron figured in two capacities. He, the speaker, was not aware that those who advocated the view against which Mr. Madan contended had ever asserted that a Latin name, if used at all, ought universally to be employed; and if English names were insisted on, they would be led into eccentricities not less remarkable than those against which the author contends. Carbon and sulphur were Latin words which, if discarded in favour of the English words, would lead to words like charcoalic oxide and charcoalic acid, and brimstonic acid and brimstonous acid, a change which did not appear to him a very great improvement. It was exceedingly desirable that everybody should bring forward his own impression in the matter, because it was only by general consent that any important system could be established.

Mr. VERNON HARCOURT thought the difficulty attaching to the choice of names was inevitable in the present state of chemistry. Either a name must be unsystematic, and merely express one or two facts about the particular substance, *e.g.*, corrosive sublimate; or, if it was systematic, and expressed a relation between the particular substance and others, it must embody a theory not yet definitely established. With reference to English and Latin names, sulphur had for so long a time been used as an English word, that it was, in reality, no less so than brimstone. The latter, he supposed, was a German word, and sulphur was, originally, Latin, but it had now become as thoroughly English as any word in the language. With regard to using *ic* and *ous*, he thought that the terminations *proto* and *per* might equally be said to express facts; and it appeared to him that the objection raised by Mr. Madan, that the terminations *-ic* and *-ous* served only for two terms of a series, and that this mode of expression cannot be extended in cases where the series extends beyond two terms was a just one. At the same time, he thought that, where there were two parallel series of salts (such as mercurous and mercuric salts, ferrous and ferric salts), it was a great convenience to have these terms, and "ferrous salts" was, perhaps, a better expression than "iron proto-salts," which Mr. Madan recommended as a substitute.

Mr. MCLEOD remarked that there was a certain excuse for the use of Latin words, for, in almost all cases, they referred to the symbol.

Dr. ODLING said that Mr. Madan spoke of the convenience which occasionally attached to their being able to use such a word as "proto-salts," and to speak of proto-salts in general. It would be a real advantage if all proto-salts were conceived to have the same constitution; but, as the word proto-salts did not express the constitution any more than *-ic* and *-ous*, he could not admit that argument to have any weight in favour of the use of such words as *proto-* and *per-* rather than of *-ic* and *-ous*. He was rather inclined to agree with Mr. Harcourt's observations in defence of the English. Respecting such words as mono-chloride and bi-chloride of mercury, it was quite true that, if they used them, they meant that the one contained double the quantity of chlorine in the molecule to the other, and not merely double the ratio of the mercury and the chlorine.

The PRESIDENT hoped it would not be understood that he insisted on Latin names in preference to the English. When Latin names were more easily modified than English, by all means use them; but, when such was not the case, refuse them. It would not be worth while to employ English words instead of the Latin aluminium, chromium, &c.; and it should not be argued that, because they used English words in some cases, that therefore they must use them in all cases. The whole genius of the English language was at variance with that proposition. They wanted an intelligible principle to guide them, instead of the fixed names, which imply particular theories of the constitution of bodies. With regard to *-ic* and *-ous* only adapting themselves to one term of a series, he conceived that, as long as they had to do with the properties of bodies in chemistry, the difference between acid and basic bodies would be one of the chief things to refer to; and, if the business of names was to recall the chief properties of bodies, he thought it must be an advantage, in describing terms of a series, to use some name to distinguish those which were not acid from those which were.

* CHEMICAL NEWS, vol. xvi., p. 272.

Professor Voelcker said that, in one aspect, uniformity of nomenclature had great advantages; but he was not sure that one and the same chemical compound, having two, three, or four different names, was an unmitigated evil. In teaching chemistry, he would not object to a substance being called by the empirical name, if, by this means, certain properties were fixed upon the mind of the student, by which he became familiar with a certain definite substance. He might afterwards be told to call it by another name, and then by a third; and, when he was once familiar with the real nature of the substance, it was immaterial whether he knew it by one name or the other. By the same combination having different names, the teacher would be able to illustrate the different views entertained by chemists of the constitution of a substance.

The next paper was on "*Results of the Analysis of Sea Water Performed on board H.M.S. Porcupine, July*, 1869," by John Hunter, M.A., F.C.S.

The first part of this paper is devoted to abstracts of papers published on this subject by Darondeau, Aime, Bischof, Hayes, Morren, and Thorpe, given by the author to show that very little has been done in investigating the gases contained in the ocean at any great depth, and that the various experiments had not yielded identical results. To collect the water for his experiments, the author used a large brass tube, attached to the sounding-line. Two valves were placed in the tube, one at the upper end, the other below, but both opening upwards, so that, when descending, the water flowed freely through, but, when drawn up, the pressure of the external water closed the valves, and the sample of the last water which had entered the tube was secured. 800 c.c. were placed in a flask, and the gases determined by boiling, according to the method of Dr. Miller. The amount of organic matter was observed by Dr. Miller's process, and the specific gravity was also taken. Two series of experiments were made. In the first, the specific gravity of the bottom water was rather less than that of the surface; but, in the second series, they were identical. The carbonic acid was found to be in greatest quantity at the bottom; it then diminished a certain amount, and remained pretty constant until within about 100 fathoms of the surface, when it diminished still more. The amount of organic matter was about the same in bottom and surface water.

At the end, Mr. Hunter gives the results of his experiments in a tabulated form.

Mr. McLeod thought that, if the absolute quantity of carbonic anhydride or carbonic acid gas in 100 volumes of water had been given, the results would then have been more comparable, and the relation between sea water and ordinary spring water would be shown. The total quantity of gas in 100 volumes of sea water was much less than he would have expected, and less than is found in ordinary river waters. Thames water, he thought, contained 6 volumes in 100 of the three gases together; while the largest proportion of gas in sea water, according to Mr. Hunter, was only 2·8 in 100. It had been stated that sea water brought from a depth effervesced like soda-water; but that would seem to be almost an impossibility if the quantity of gas obtained was as low as 2·8. It was just possible that, in collecting the water, if there was any pressure in the tube, it would open the upper valve, and allow nearly all the gas to escape; but he (Mr. McLeod) was not in a position to suggest a better apparatus than the one described.

The President thought that, if it were soda-water below, they ought to cork it up before bringing it to the surface; but the results obtained by Mr. Hunter did not agree with the soda-water theory. He did not see that the gas should have any tendency to come off from the water, when there was so little of it there; but the quantities might not, perhaps, have been so great as reports made of experiments would lead one to expect.

The Society then adjourned to the 16th inst.

ROYAL INSTITUTION OF GREAT BRITAIN.

General Monthly Meeting, Monday, December 6, 1869.

George Busk, Esq., F.R.S., in the Chair.

George Henderson Gibb, Esq., William Harbottle, Esq., John Henderson, Esq.; and Henry Musgrave Musgrave, Esq., were elected Members of the Royal Institution.

The following lecture arrangements for the ensuing season were announced:—

Professor Tyndall, LL.D., F.R.S.—Six lectures (adapted to a juvenile auditory), "On Light." On December 28th, 30th, 1869; January 1st, 4th, 6th, 8th, 1870.

Before Easter, 1870.

Professor Humphry, M.D., F.R.S.– Six lectures, "On the Architecture of the Human Body." On Tuesdays, January 18th to February 22nd.

Professor Odling, F.R.S.—Twelve lectures, "On the Chemistry of Vegetable Products." On Thursdays, January 20th to April 7th.

Robert Scott, Esq., M.A., Director of the Meteorological Office.—Four lectures, "On Meteorology." On Saturdays, January 22nd to February 12th.

Dr. Masters, F.L.S.—Two lectures, "On Plant Life as Contrasted with that of Animals." On Tuesdays, March 1st and 8th.

Professor Rolleston, M.D., F.R.S.—Four lectures, "Deductions from the Comparative Anatomy of the Nervous System." On Tuesdays, March 15th to April 5th.

Professor Max Müller, M.A., LL.D.—Four lectures, "An Introduction to the Science of Religion." On Saturdays, February 19th to March 12th.

Joseph Norman Lockyer, Esq., F.R.S.—Four lectures, "On the Sun." On Saturdays, March 19th to April 9th.

After Easter.

Professor Blackie.—Four lectures, "On the Principles of Moral and Political Philosophy." On Tuesdays, April 26th to May 17th.

Professor Tyndall, LL.D., F.R.S.—Seven Lectures, "On Physics." On Thursdays, April 28th to June 9th.

Professor Robert Grant, LL.D., F.R.S.—Seven lectures, "On Astronomy." On Saturdays, April 30th to June 11th.

Professor Seeley.—Three lectures, "On History." On Tuesdays, May 24th, 31st, and June 7th.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

MICROSCOPICAL AND NATURAL HISTORY SECTION.

November 8, 1869.

Joseph Baxendell, F.R.A.S., Vice-President of the Section, in the Chair.

The following note was read from Mr. Joseph Sidebotham:—

About fifteen years ago, I had a large cabinet, made of forty-five drawers, to contain shells and carpological specimens, the drawers being made of pencil-cedar. Very soon I found that the resinous vapour from the wood became deposited on some of the fruits and shells, making them appear as if they had been dipped in varnish. Chloroform appeared to be the only solvent, and the specimens were obliged to be washed with it. This became so bad that I had the whole of the drawers removed, and replaced with drawers of bay-wood. Some time afterwards, Mr. Carter advised me to have the cedar drawers sized and papered inside, and a new cabinet made to contain them. Accordingly, he made me one to contain thirty drawers. These drawers were exposed to the air for twelve months, and very well sized inside, and

papered; but the resinous vapour is still deposited on the objects in the drawers as before, and, so far, is a warning to every one never to use pencil-cedar for such a purpose. I should not, however, have thought this matter worthy of mention before the Section, had it not been for the very curious and capricious way in which some objects are coated with this resin, while others are left entirely free, and for which I am totally unable to account. In shells, the genera *Conus* and *Oliva* are never touched by it, nor are *Cyprea* or *Mitra*, whilst *Helix*, *Bulimus*, and *Pecten* are coated over. This is the case when there are specimens of these and other genera in the same drawer. As this deposit is on the genera I have named, and never on the others, it would seem to indicate that the texture of some shells would attract the vapour, and not others; but, in the case of birds' eggs, the very strange manner in which some species are picked out, as it were, and others left, is most remarkable. In the owl's eggs, for instance, the barn owl is always free, while the tawny owl is covered with the varnish, although side by side. The song thrush is never attacked, and the missel thrush always.

Trays exhibiting these peculiarities were passed round for inspection.

GLASGOW PHILOSOPHICAL SOCIETY.

(Chemical Section).

The ordinary meeting of the Section was held on the evening of Monday, December 6th, Mr. William R. Hutton, Treasurer, presiding. Several candidates were proposed for admission, and several others were ballotted for.

The first paper read was entitled, "*Note on the Action of House Sewage on Lead Pipes.*" In introducing it, the author,

Mr. Edward C. C. Stanford, F.C.S., referred to the panic which had recently been shown by the voluminous correspondence in the local papers regarding the alleged impurity of the water used for domestic purposes, and stated that it had revived the old question of the action of the purer kinds of potable water on the lead of the pipes and cisterns. The panic, known locally under the name of "death in the cistern," had been completely allayed by the remarkable unanimity of the reports prepared by Dr. Anderson, Professor of Chemistry, and Dr. Wallace, Analytical Chemist, and backed by an eminent medical authority like Dr. W. T. Gairdner. Notwithstanding, however, that the amount of lead was small, a sufficient quantity had been found in almost all the analyses of the cistern water to show the desirability of avoiding all suspicion of lead contamination, by adopting a constant high-pressure service in iron pipes, and, where they are required, of using cisterns of iron or slate. The author remarked that much attention had, from time to time, been directed to the action of the purer kinds of potable water upon lead; but it was somewhat remarkable that an equally-important and much wider-spread evil of a similar character had escaped notice. He referred to the serious deterioration which lead pipes undergo which are connected with water-closets; and he brought this subject under the notice of the Section in order that some light might be thrown upon the cause of the said deterioration. Dr. Fergus, a Glasgow medical gentleman, had the credit of first directing attention to the subject by tracing a close connection between the deterioration of the soil-pipes and the existence of various forms of low febrile disease in the houses into which, from the degenerated condition of the pipes, sewer gases make their escape. By means of sketches and used-up specimens of soil-pipes, the author showed the nature of the action to which the pipes are subject from long use—the length of time varying from ten to sixteen years. Near the bend of the pipe leading from the closet the upper part becomes coated with a greyish white deposit that can be easily scraped off, and the interior of the pipe becomes pitted; while, exteriorly, the pipe is at first blistered at the parts corresponding to the internal "pits," and in course of time it becomes quite riddled with holes, and quite gnawed away as it were. Mr. Stanford had analysed samples of the deposit from several soil pipes, and had found from 86 to about 93 per cent of the deposit to consist of plumbic carbonate, the other ingredients being calcic carbonate, silica, insoluble plumbic oxide, water, and organic matter. After noticing the chemical compounds which, in solution in water, act readily upon lead, the author said that the deterioration referred to was not due to those substances, inasmuch as they were found in the excreta, whereas the injury to the pipes took place in the air-space of the bend, and not in the water-space in which the "trapping" was effected. It has been remarked by plumbers, that a piece of lime, or newly-mixed mortar, in contact with a pipe, rapidly eats through it, probably by the lime combining with the carbonic acid of the outside film, and so cleaning the lead that the action of the air repeats the process. In the opinion of the author, alkalies would probably have the same effect as lime, and so clean the lead that a moist atmosphere would act on it. The effect of pure water on lead is first to dissolve it as oxide, and then this is precipitated as oxycarbonate, which is very insoluble, pure water only dissolving 1-60th of a grain per gallon. Water free from air does not act on lead; and the author therefore thought the action referred to might be due to the air carried down by the rush of water while the closet was acting, and by the carbonic acid, or by the ammonia of the gases of decomposition acting as a cleaner, the interior of the pipe being always in a moist condition. Mr. Stanford concluded by recommending the discontinuance of lead soil pipes, and the substitution of earthenware syphons and flanged cast-iron pipes.

Dr. Fergus, in opening the discussion, recommended that soil pipes should be ventilated, or that they should be used as the rain-water pipes. He gave some instances, in his professional experience, of the connection between such diseases as gastric fever, diphtheria, &c., and bad soil pipes; and he strongly urged the periodical investigation of such pipes.

Mr. Sutherland suggested that the action might be due to sulphuretted hydrogen or acetic acid; but Mr. Stanford said that plumbic sulphide had never been found in his analyses.

Mr. Anderson believed that nitric acid, resulting from the oxidation of ammonia, might have some influence in producing the injurious effects on the pipes. This view was supported by Mr. Hutton and Mr. Tatlock. The first-mentioned gentleman referred to experience extending over sixteen years, and said that Loch Katrine water is very peculiar, in having an abundance of dissolved oxygen and very little carbonic acid, and that such water rapidly acts on lead, producing oxycarbonate, which is readily soluble in fresh water from the same source.

Mr. Stanford replied that he had never met with nitrates in the course of his experiments.

A vote of thanks was awarded to Mr. Stanford.

A paper was then read by Mr. R. T. Tatlock, F.C.S., "*On the Estimation of Iodine and Bromine, with special reference to the Analysis of Kelp.*" We are compelled to hold over this paper for a week.

ROYAL IRISH ACADEMY.

The general meeting of this society was held on Tuesday, November 30th, Right Hon. the Earl of Dunraven in the chair.

The first business was the election of a president, in room of Lord Talbot de Malahide.

Dr. Loyd, Provost of Trinity College, moved that the Rev. John Jellett, F.T.C.D., be elected president. He said that Professor Jellett's high scientific claims were thoroughly known by the members of the Academy, before which body his investigations had been brought. In the higher abstract sciences, Professor Jellett was second to none in this part of the empire, with the exception of one, who had retired, and he combined scientific attainments which were not often found in the same man. Dr. Stokes, in the absence of Dr. Russell, President of Maynooth, seconded the motion. Professor Jellett was duly elected by ballot. This election gives general satisfaction, as it has been felt for some time past that the scientific element in the Academy "has not," as the Earl of Dunraven expressed it, "taken the position that was its right."

Sir WILLIAM WILDE then read a paper upon "*A Collection of Gold, Bronze, and Iron Antiquities Found in Excavations made for the Supplying of Gravel to the City.*" They were supposed to be of Scandinavian origin.

Dr. APJOHN then read a paper "*On the Proximate Analysis of Saccharine Substances.*" In this method, the author makes use of the optical and chemical processes, and thus quantitatively determines the amount of cane sugar, inverted sugar, and grape sugar in a given sample. An extended report of this paper will shortly be given in the CHEMICAL NEWS.

NOTICES OF BOOKS.

The Students' Chemistry; being the Seventh Edition of Household Chemistry, or the Science of Home Life. By ALBERT J. BERNAYS, Ph.D., F.C.S., Professor of Chemistry and of Practical Chemistry at St. Thomas's Hospital Medical and Surgical College, &c., &c. 1869. W. H. Allen and Co.

THE well-known and popular work of Dr. Bernays has, in this new edition, been so completely altered and recast that it is, in point of fact, a new book. The experiment of altering the form of a work which has met with such marked favour from the public is a bold one, but we have no hesitation in predicting that, in the present instance, it will be entirely successful.

The book, in its present form, has no longer the popular and readable character that it formerly possessed; but, on the other hand, it is now, what it never was before, a systematic and complete manual for students. It is very lucid in style and practical in matter. It contains a vast mass of fact simply and accurately stated, and bound together by just as much theory as is necessary for the understanding and remembering of it. The notes with which each chapter is headed are very clear and full, and will assist the labours of the student most materially. The author promises to devote a second volume to organic chemistry and to the theories of the science, and confines the present one to inorganic chemistry.

If this second volume is as good as the first, it will be a very useful book.

CORRESPONDENCE.

COAL DYES IN 1818.

To the Editor of the Chemical News.

SIR,—I read in *Blackwood's Magazine*, for June 1818, p. 339, the following paragraph, which may, perhaps, be interesting to many of your readers:—

"*New Extracts from Coal.*—Dr. Jassmeyer, Professor of Chemistry in Vienna, has discovered the means of extracting from coals two hitherto unknown acids, a resin, a resinous gum, and other elements, which he has employed with surprising success to the purposes of dyeing wool, silk, hair, and linen, and has produced from them red, black, yellow, and various shades of brown and grey. Count von Chorinsky, President of the Aulic Chamber, and many other enlightened judges of these matters were present at these experiments, and testified their entire approbation of this useful discovery."

Can any of our brother chemists inform us whether these products are known at the present day, and under what names?—I am, &c.

T. L. PHIPSON, Ph.D., F.C.S.,
Member of the Chemical Society of Paris.

Analytical Laboratory, Putney, S.W.
November 29, 1869.

MISCELLANEOUS.

University of London.—*Second B.Sc. Examination (Examinations for Honours, B.A. and B.Sc. conjointly).*—Mathematics and Natural Philosophy: First Class. Richard Pendlebury, B.A. (scholarship), St. John's College, Cambridge. Logic and Moral Philosophy: First Class. Matthew Robertson, B.A., New College; Walter William Rouse Ball, B.A., University College. Third Class. Arthur Clarke, B.A., Wesley College, Sheffield; Alfred Milnes, B.A., Manchester New College; James Greaves, B.A., private study; Frederick de Sola Mendes, B.A., University College; and Stephen Peter Hayes, B.A., Stonyhurst College, and Henry Keatley Moore, B.A., private study (equal). (*B.Sc. only.*)—Chemistry: First Class. Alexander Muirhead, University College. Second Class. Charles Thomas Whitmell, St. John's and Trinity Colleges, Cambridge. Geology and Palæontology: First Class. Charles Thomas Whitmell, St. John's and Trinity Colleges, Cambridge; Frederick Antony Potter, Royal School of Mines. Zoology: First Class. Phineas Simon Abraham, Trinity College and Royal College of Science, Dublin. Second Class. William Henry Johnson, University College.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, *with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."*

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, November 29, 1869.

This number contains the following memoirs and papers relating to chemistry and allied sciences:—

Construction of an Optical Plane.—M. Foucault.—It appears that M. A. Martin has found, among the papers left by the deceased author, a short note on the proper means to realise the construction of an optical plane—that is to say, a plane surface so perfect that the reflected ray of light in no respect differs from the incident ray.

Improving Wine by Electricity.—M. Scoutetten.—The author states that the accidental striking of lightning on the house of a vineyard proprietor caused the rupture of several large hogsheads containing wine, which found its way into a cavity existing in the cellar of the house. The owner imagined his wine lost and spoiled, but found, to his astonishment, that the wine, instead of having been deteriorated, had become better than it was before. This accidental occurrence having come to the knowledge of General Marey-Mouge, caused the author of this paper to be consulted, and a series of experiments were instituted with various kinds of wine, of inferior as well

as medium quality, the result being that a galvanic current, applied to the liquid in the casks, both electrodes consisting of platinum plates, eminently improves even very inferior kinds.

Rendering Rivers Wholesome.—M. Gérardin.—According to this author, the fouling of rivers and water-courses is greatly due to the starch manufactories situate along the same, in consequence of the discharge of water containing up to 7 and 8 per cent of albuminous matter, which soon enters into decay, giving rise to the formation of myriads of lower forms of animal life, which withdraw from the water its dissolved oxygen, and hence cause the destruction of higher organised plants and animals.

Researches on Solar Radiation.—MM. Desains and Branly.—This paper, and the following—

Expansion of Gases—M. Moustier—Are not well suited for useful abstraction.

Molecular Action in Atmospheres of Chlorine, Bromine, and Iodine.—M. Valson.—This memoir contains the results of a series of experiments relating to the capillary action of chlorides, bromides, and iodides in aqueous solution and immersed in gas or vapour of the haloids above mentioned. The results are exhibited in tabulated forms.

New Method for the Preparation of Anhydrous Nitric Acid.—MM. Odet and Vignon.—The authors refer first, at some length, to the now well-known, yet difficult and highly delicate, method of obtaining anhydrous nitric acid, discovered by M. H. St. Claire-Deville. The authors obtain this compound by causing chloride of azotyl to act upon perfectly dry nitrate of silver at from 60° to 70°. Chloride of azotyl is prepared by the action of oxychloride of phosphorus upon nitrate of lead, or, better yet, nitrate of silver. The chloride of azotyl is a slightly yellow-coloured liquid, boiling at 5°, and not frozen at −31°; in contact with water, this substance is decomposed into nitric and hydrochloric acids. The vapour of this fluid is applied for the decomposition of dry nitrate of silver, in a simple apparatus consisting of U-shaped tubes soldered together by means of suitably-bent glass tubes. The chloride of azotyl is prepared simultaneously with the anhydrous nitric acid, which is collected in a tube placed in freezing mixture at −25°.

Preparation of Hydrate of Chloral.—M. Roussin.—The mode of preparation here described is precisely the same as that already well-known, and lately quoted by us from a German paper. Pure hydrate of chloral is a snow-white crystalline substance, not exhibiting any smell at the ordinary temperature of the air; it volatilises slowly, without absorbing much moisture, unless it be placed in a very damp place; fuses at 56°; boils at 145°; is completely soluble in a small quantity of water, and also soluble in alcohol, ether, chloroform, sulphide of carbon, benzine, and fatty substances. Its aqueous solution ought to be neutral to test paper, and ought not to become turbid by a solution of nitrate of silver. When, to this aqueous solution of hydrate of chloral, a few drops of a solution of caustic potassa are added, there is formed chloroform, easily recognised by its peculiar smell.

So-called Inverted Sugar.—M. Dubrunfaut.—There is appended to this paper a short foot-note, from which it appears that there belong to it two papers not printed yet, by M. Maumené, without which this subject is not complete.

Radiation from the Moon.—M. Marié-Davy.—A third memoir on the much-vexed question about the heat given off by our satellite. This memoir is a purely mathematico-physical essay.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 16, 1869.

The president, Dr. A. W. Hofmann, opened the ordinary meeting, from the *procès verbal* of which we learn the following items:—Among the ordinary members elected, we find the name of Prof. Chandler, of New York. Prof. Baumhauer, of Haarlem, promises to send to the Society a regular account of all that is done on chemical territory in the Netherlands. The president exhibits several samples of partly crystallised tin, received from M. Fritsche, of St. Petersburg; this crystallisation is the effect of a continued exposure for three hours of the metal to a temperature below the freezing point of mercury. When the metal is exposed for any length of time to this low temperature, it falls completely to a greyish coloured powder; when this powder is heated to 100°, it becomes whitish-grey coloured. The president exhibits several photograms representing partially-crystallised organ-pipes, which had been inspected and photographed by the late Prof. Erdmann. We may mention here that this crystallisation of the tin whereof organ-pipes are made is by no means an uncommon phenomenon, and one not solely due to cold alone, but, in a great measure, to the vibration these pipes are subject to. The president exhibits a number of samples of wool, dyed green with the so-called iodine green, by M. T. Peters, of Chemnitz, and hands round to the members circulars issued by that dyer, and printed in German, French, and English, on the best method of applying this dye.

Preparation of Hydrate of Chloral.—MM. Müller and Paul.—The chief part of this operation consists in passing a current of dry and pure chlorine gas into pure and absolute alcohol, until the contents of the flask are, after about 70 hours, converted into a white and crystalline mass; when this operation is properly conducted, a large quantity of hydrate of chloral is obtained. The authors state that they had found by experiment that the hydrate of chloral is readily sublimed, and may be thus obtained as a dry, snow-white, neutral crystalline powder.

Relation of Mercury-Phenyl to the Aromatic Series.—MM. Dreher and Otto.—Mercury-phenyl is formed by the action of $HgNa_2$ upon C_6H_5Br—

$$2(C_6H_5Br)+HgNa_2 = \left\{\begin{matrix}C_6H_5\\C_6H_5\end{matrix}\right\}Hg+2NaBr.$$

The addition of a small quantity of acetic ether greatly promotes the reaction. ClH, IH, and BrH decompose—

$$\left\{\begin{matrix}C_6H_5\\C_6H_5\end{matrix}\right\}Hg,$$

according to the following equation:—

$$\left\{\begin{matrix}C_6H_5\\C_6H_5\end{matrix}\right\}Hg+2HCl=HgCl_2+2C_6H_6.$$

By the action of chlorine, bromine, and iodine, it is not easy to obtain from mercury-phenyl the respective chlorinated, bromated, and iodated compounds; the reactions and decompositions which take place are represented by the following formulæ:—

$$\left\{\begin{matrix}C_6H_5\\C_6H_5\end{matrix}\right\}Hg+2Cl=\left\{\begin{matrix}C_6H_5\\Cl\end{matrix}\right\}Hg+C_6H_5Cl;$$

when chlorine was made to act upon—

$$\left\{\begin{matrix}C_6H_5\\Cl\end{matrix}\right\}Hg+2Cl=C_6H_5Cl+HgCl_2.$$

We refrain from further abstraction of this lengthy paper, which is chiefly composed of a mass of formulæ.

Phosgene.—MM. Emmerling and Lengyel.—This paper is divided into three sections:—(1) *Conversion of carboxysulphide into phosgene.*—Chlorine does not act upon carboxysulphide at the ordinary temperature; but when a dry mixture of both gases is made to pass through a red-hot porcelain tube filled with fragments of broken porcelain, a gaseous mixture of CO, $COCl_2$, SCl_2, and unchanged Cl and COS. In order to recognise the phosgene, and estimate its quantity, the gaseous mixture just alluded to was passed through tubes filled with black sulphuret of antimony, this serving the purpose of separating the phosgene from various admixtures. For the purpose of analysis, the gas was collected in tubes, inside of which a small glass globe was placed, filled with a solution of caustic potassa. After the tubes had been filled with the gas, and sealed, this glass globe was broken (its walls being very thin), by shaking the tube in the fluid contents. After a time, the relative proportions of Cl and S were determined, and in other portions of the gas the CO was separately estimated. (2) *Preparation of phosgene from chloroform.*—This fluid is split up by the action of sulphuric acid and bichromate of potassa, yielding phosgene—

$$2CHCl_3+3O=2COCl_2+H_2O+Cl_2.$$

Forty parts of strong SO_3, five parts of bichromate, and two parts of chloroform yield, when heated on a water-bath, a phosgene free from oxygen. (3) *Fluid phosgene.*—This was obtained by passing the gas through an U-shaped tube placed in ice. The fluid gas is very volatile, and specifically heavier than water, by which liquid it is decomposed, evolving CO_2.

Under the title of "Correspondence," we meet with a first instalment of a report about the meeting at Inspruck, held in September last. Leaving the excellent and thoroughly German and enthusiastic general account of this meeting, we learn that the chemical section was presided over by Prof. Hlasiwetz, of Vienna, and that eighty-six members regularly attended, while the audience was even rather too large for the large chemistry lecture-room of the University wherein this section met. The following subjects were treated:—

Origin (Entstehung) of Iodoform, and the Applicability of the Formation of Iodoform for Analytical Purposes.—M. Lieben.—Iodoform is, according to this author, the most delicate test for alcohol, provided such substances be absent as might happen to exhibit the same reaction. In ether, even when distilled over sodium, alcohol can be detected by iodoform; and there is no doubt, the author says, that alcohol is formed in all ether which contains or can absorb water. Only those substances which contain CH_3 are capable of forming iodoform.

Modifications of Lactic Acid.—Dr. Wislicenus.—According to the author, there exist three modifications of oxypropionic acid. The lactic acid of fermentation, ethyliden lactic acid, differs from the ethylen lactic acid, and is easily obtained from β iod-propionic acid. The lactic acid of muscles differs from the two alluded to, but is not a chemical individual, since it is made up of ethylen lactic acid and a peculiar modification of ethyliden lactic acid.

Phenicin.—Prof. Bolley.—The substance known as phenicin, a brown colouring dye, also known as phenyl brown, is made by adding phenol to a mixture of nitric and sulphuric acids, and by pouring this mixture afterwards into a large bulk of water, when the phenicin is obtained as an amorphous powder. The manufacture of this preparation has given rise already frequently to serious explosions. The author found that the commercial article, as well as the pure article (phenicin), contains binitrophenol, a brown amorphous substance, which is neither a nitro nor a sulpho compound, and produced, it appears, by the action of sulphuric acid upon binitrophenol.

Proteine Compounds.—Dr. Schwarzbach.—The author states that the differences found by many experimenters, in the reaction of the potassio-platinum cyanide with the proteine compounds, is due to the fact that, instead of the Gmelin salt, that of Quadrat has been applied.

Preparation of Iodine Substitution-Products.—Prof. Hlasiwetz.—To the substance which is to be iodised, peroxide of mercury

is added, and the requisite quantity of iodine is added afterwards. The researches on this subject are not quite complete.

At the meeting of the Russian Chemical Society, held on the 2nd of October (O.S.) last, the following communications were made (communicated by M. von Richter, St. Petersburg):—

Benzimide.—M. Zinin.—The so-called benzimide of Laurent, $C_{28}H_{18}N_2O_2$, which is formed by the action of hydrocyanic acid upon essential oil of bitter almonds, is converted, when heated to from 160° to 180°, into an amide—

$$C_{28}H_{18}O_2N_2 + H_2O = C_7H_6O + C_{16}H_{14}O_2N_2,$$

and into a nitrogenous compound, which is the imide of formobenzilic acid.

Bromocamphoric Acid.—M. Wreden.—When dry camphoric acid is heated with bromine to 120°, monobromocamphoric acid anhydride, $C_{10}H_{13}BrO_3$, is obtained. This substance is nearly entirely insoluble in water, alcohol, and ether, at ordinary temperature; it sublimes at about 60°, but is also partly decomposed at that temperature. When this anhydride is boiled with water, a new acid, $C_{10}H_{14}O_4$, is obtained; this acid is readily soluble in water, alcohol, and ether, crystallises from its aqueous solution, sublimes at 110°, and fuses at 201°. The lead and copper salts of this acid are soluble in water; the soda-salt is a very deliquescent substance.

Valerian Aldehyde and Œnanth Aldehyde.—M. Borodin.—When the two substances just named are heated to 240° in sealed tubes, several products of condensation can be directly obtained; the reaction goes on steadily, water is formed, no resinification takes place, and, on opening the tube, no pressure is experienced. The valerian aldehyde yields, when submitted to fractional distillation, two oily fluids, one of which boils at from 195° to 200°, the other at from 180° to 200°. The analysis of these substances proved the first to be the condensation product of two molecules of aldehyde, from which one molecule of water was expelled; the other substance is a polymer of the last-named.

Atomic Weights.—M. Mendelejeff.—This paper contains a new plan of grouping the elements, according to the numerical value of their atomic weights, in the following manner:—Li, 7; Be, 9·4; B, 11; C, 12; N, 14; O, 16; Fe, 19; Na, 23; Mg, 24; Al, 27·4; Si, 28, and so on; but there is a considerable hiatus between Cl, 35, and the next, Ag, 108. The author points out that this grouping of the elements expresses the law according to which the elements can combine with oxygen.

On Xylidine.—M. Tawildarow.—The author prepared xylidine from isoxylol, which was obtained from coal-tar xylol by boiling that substance with dilute nitric acid. The nitroisoxylol thus obtained was reduced by means of tin and hydrochloric acid, and the xylidine purified by means of caustic potassa; the substance thus obtained is a colourless fluid, boiling at 216°; sp. gr. at 18°, 0·985. The oxalate of xylidine crystallises, and is somewhat soluble in water. When xylidine is submitted to distillation, a solid matter is left, which, on being heated to about 240°, yields a substance soluble in alcohol, crystalline, and fusing at 89°; this is a basic substance containing chlorine; its hydrochloric acid compound has the following composition:—$N(C_8H_8Cl)_3.HCl$. 100 parts of xylidine yielded about from two to three parts of this material.

Polytechnisches Journal von Dingler, second number for October, 1869.

This number contains the following original papers relating to chemistry and allied sciences:—

Blast Furnaces constructed for the Continuous Flowing Off of Slag.—M. Lürmann.—This paper contains the description of an improved blast furnace for ironworks. From a foot-note added to the paper, we learn that the Old Park Iron Company, Shropshire, have adopted the improvements invented by this author, and are highly satisfied with the results.

Chemistry of the Blast Furnace.—M. Schinz.

Manufacture of Steel for the Use of Rifle Guns and Heavy Ordnance at the Works of M. Cockerill, at Séraing.—M. Greiner.—The author states that, at Séraing (near Liège, Belgium), the following three points are rigorously attended to as regards the manufacture of steel for the purpose indicated:—Purity of product; homogeneity thereof; and the exercise of proper control to ensure these requisites. It appears that this branch of manufacture is attended to in a thoroughly scientific manner, the use of the spectroscope, and of chemical analysis and assays, being matters of daily application. The test for carbon is executed in the following manner:—Of two samples of the same kind of steel, 0·2 grm. are placed in beaker-glasses of fully 20 c.c. capacity, and treated with nitric acid of 1·2 sp. gr.; the glasses are kept for four hours on a water-bath, and heated to 80°. The solutions assume a brownish yellow colour, which is compared with the colour which two other solutions of the same quantity of steel, containing a known quantity of carbon (0·61 and 0·63 per cent), assume after the four solutions have been all diluted with the same quantity of pure water. Suppose the solutions of steel containing known quantities of carbon to be respectively diluted to 252 and 260 c.c., and the solutions of the steel under examination to 142 and 144 c.c., the following calculation will give the required result:—

$$\frac{142 \times 61}{252} = 34{\cdot}33; \quad \frac{144 \times 63}{260} = 34{\cdot}90;$$

therefore the average = 34·615 = 0·346 per cent.

Boiler Incrustation, from Lillschacht, near Pribram.—Dr. Mrazek.—The author obtained for analysis and investigation a quantity of a very white, compact, micro-crystalline substance, which was stated to be the incrustation found in a steam boiler fed with water pumped from a mine. On being analysed, the stone was found to consist, in 100 parts, of:—Lime, 33·60; sulphuric acid, 47·41; magnesia, 12·26; water, 5·52; impurities, 0·79. This result leads to the formula $2(CaO,SO_3)+(MgO,HO)$, constituting, in fact, a mixture of anhydrite and brucite. The analysis of the water proved it to contain, in 10,000 parts—Sulphuric acid, 5·51; lime, 3·40; magnesia, 0·23; with traces only of chloride of sodium and soluble organic matter. The author also obtained a quantity of mud taken from the same boiler; this mud was found to consist, in 100 parts, of—Anhydrite, 14·24; hydrated magnesia, 2·27; lime, 16·49; carbonic acid, 12·06; clay, particles of quartz, oxides of metals, and metallic sulphides, 30·26; particles of wood and water (the former predominating), 23·78. The author states in this paper that if, in the case of boiler explosions, it is possible to obtain some of the incrustation of the exploded boiler, the analysis of that incrustation may lead to the detection of the cause of the explosion; if due to the want of water, and the boiler-plates becoming red-hot, the exact estimation of the water chemically combined with the incrustation is sufficient, since, if the boiler had been red-hot, the whole of the water of combination will have been expelled.

Apparatus for the Safe Keeping and Transport of Petroleum, Benzol, &c.—Dr. Tech.

Application of Iridium for Staining Glass and China.—M. Frick.—It appears that pure oxide of iridium yields, upon glass and china, a black-coloured stain of so intense and deep a tone of shade that the other substances in use for that purpose are, compared with this colour, of a brownish hue. The pure oxide of iridium is obtained, especially as a bye-product, in the purification of American platinum ores, and may be obtained from M. Röszler, at Frankfort-on-the-Maine.

Moniteur Scientifique, November 15, 1869.

Artificial Alizarine.—M. Bolley.—There are at present already three artificial products which come into competition with madder and its various preparations, viz.:—(1) It appears that MM. Græbe and Liebermann have stated, at the congress of German *savants* lately held at Insprück, that they can dispense with the use of acetic acid and bromine, and will be enabled shortly to bring into the trade a superior product, made by a method different from that described in their patent, and that this new product will be manufactured at Manheim by a celebrated firm of aniline colour makers. (2) Artificial purpurine and alizarine, made by MM. Broenner and Gutzkow, according to their patent, by the action of protonitrate of mercury upon anthrachinon; this process is carried on at Frankfort-on-the-Maine. (3) Artificial alizarine (alizapurine, according to M. Alfraise), prepared, by a process as yet kept secret, by MM. Meister and Lucius, at Hoechst, near the same city just named. The author of this paper just named states that he received from M. Riese, the head chemist to the firm just alluded to, at Hoechst, a quantity of 500 grms. of the paste (artificial alizarine) in question, with the request to assay it and report thereon. This substance exhibits a greenish brown-coloured, rather fluid paste, containing about 6 per cent of dry solid matter; when this dry substance is cautiously submitted to an elevated temperature, a brick-red coloured sublimate is obtained in needle-shaped crystals, a bulky carbonaceous residue is left, and, on igniting this, the ash is found to contain a large proportion of oxide of iron. The sublimate dissolves in caustic soda, exhibiting a very deep blue-violet colour; this solution yields, by the addition of chloride of barium, a bluish violet-coloured precipitate, which resembles, in a high degree, the precipitate obtained under similar conditions from the alizarine of madder. The ammoniacal solution of the sublimate, and the precipitate formed therein by the baryta-salt, also, resemble the reactions obtained from native alizarine from madder under the same conditions. The sublimate referred to yields, on being boiled with a solution of alum, a partial solution in alum, but the dissolved material precipitates on cooling, and the fluid then exhibits only a rose-red colouration; it would accordingly appear that the sublimate consists mainly of alizarine, mixed with very little purpurine. The results of elementary organic analysis of this substance are quoted as follows, three analyses having been made, and the carbon and hydrogen only put down percentically:—C, 69·23; H, 3·38; C, 66·04; H, 3·28; C, 66·46; H, 3·39. The composition of purpurine, according to M. Schutzenberger, $C_{20}H_{12}O_7$, requires percentically—C, 65·93; H, 3·29. Alizarine dried at 100° is, according to Dr. Schunck, percentically—C, 69·13; H, 4·03; and, according to MM. Bolley and Rose—C, 69·54; H, 3·75. The author infers, from these facts, that the sublimate holds a composition intermediate between alizarine and purpurine; that the first portions of the sublimate above referred to contain more, or, rather, approach more to, alizarine, and the latter portions more to purpurine. On comparing the tinctorial properties of this sublimate with those of alizarine obtained from madder, the following was observed:—(1) In the dry state, the artificial alizarine in question is less suitable as a dye than when it is in paste; (2) its tinctorial power, when dry, is at least equal to one-and-a-half times the same weight of raw (green) alizarine from madder, as prepared by M. Kopp's process; (3) the artificial alizarine dyes mordanted cloth rapidly, but soils the white grounds more than green alizarine; (4) the red is very brilliant and pure after cleansing (*avivage*); (5) the violet assumes, after cleansing, a greyish hue, and the puce and black are excellent. All these colours are fast, and in no way inferior to those obtained from madder. According to the author, the experiments instituted by MM. Alfraise and C. Kœchlin, with the view to prove that the preparation alluded to, and produced by MM. Meister and Co., is neither alizarine nor purpurine—are not made with sufficient care, and with

a too impure material (the paste only) to deserve the required confidence. As regards the tinctorial power of the paste, also, this appears to have been overrated by M. C. Kœchlin.

Dyeing with so-called Iodine-Green Paste on Wool.—M. Kalle.—This author, wholesale manufacturer of artificial dyes at Biebrich (Nassau, Prussia), states that, having read the communication on the process described by M. Peters in the number of the 1st of November last of this periodical, he feels obliged to point out the following defects in that communication:—(1) When the workman does not happen to use great skill and precaution, the green does not completely dissolve in acidulated water; hence there is a loss of colouring matter. (2) When the colouring matter does not dissolve completely, filtration has to be resorted to, which it is best to avoid. The author next gives the following directions, referring, however, to the use of a pure paste only:—The paste is mixed up with one or two parts of cold water (the quantity of water depends upon the state of concentration of the paste; if the latter happens to be very fluid, or, what amounts to the same, poor in colouring matter, the addition of water is unnecessary), from six to eight parts of alcohol are added, and the mixture well stirred up. *Impregnation tincture.*—The dye-bath ought to contain, for 1 kilo. of green in pasty state (price 50 francs, £2), 1 kilo. of silicate of soda of 30 per cent strength, and is brought to the boiling point. When this has been reached, the alcoholic solution of the green above alluded to is poured into the bath, and the wool thoroughly worked through it, without more heating, until the desired shade has been obtained; the wool is next drained, wrung out, and washed in cold water, and then only brought into the developing bath composed as described by M. Peters. The author adds that the developing bath becomes gradually saturated with dye-stuff, and then unfit for use for clear shades of colour; when this point is reached, the liquid is filtered, neutralised with ammonia, a fresh quantity of silicate of soda is added, and the liquid so obtained used as a dye-bath.

Preparation of Victoria Yellow (Binitronaphthol).—MM. Darmstädter and Wichelhaus.—One part of naphthaline is mixed with two parts of concentrated sulphuric acid, and heated on a water-bath until the solution is complete; the sulpho-naphthalic acid so obtained is saturated with soda, and the solution is evaporated to dryness. The sulphonaphthalate of soda is next fused with caustic soda, and the mass resulting from this operation is dissolved in water and supersaturated with HCl, whereby naphthol, or hydrate of naphthyle, is separated. This substance is next boiled with a mixture of sulphuric and nitric acids, yielding binitronaphthol, the yellow colouring matter; this substance is chemically different from, but, after all, isomeric with, the so-called Martius yellow, or binitronaphthylic acid. The formula, $C_{20}H_6.N_2O_{10}.O_2$, answers for both equally well; industrially speaking, both substances approach each other to such a degree that they may be considered identical; both are best used in the state of ammoniacal salt, this being the most readily soluble salt for each. These materials are employed at Paris for the adulteration of gamboge, and very largely used for the colouration of artificial flowers, leather gloves, &c.

Manufacture of Carbonic Acid on the Large Scale.—M. Dietz.—After reviewing several processes in use for this purpose, the author describes, at great length, a process in actual use at Kama, near Tschistopol, Russia. The gist of the description is that the gas given off by a lime-kiln heated with wood is used as a source of carbonic acid for converting carbonate of soda into bicarbonate. During twenty-four hours, 900 cubic metres of carbonic acid gas are consumed, and the combustion of the wood used for heating the kiln is so regulated as to yield a portion of that gas along with that obtained from the limestone; wood, however, in that locality, is almost a waste material, being extremely abundantly found.

Grotto of the Dead.—We notice the title of this paper, which contains a very interesting description of the Baumo das Morts, near Durfort, Departement Du Gard, France. For the study of the earliest age of man's appearance on the globe, this is a valuable contribution.

Journal für Gasbeleuchtung, Nos. 9 and 10, 1869.

These numbers contain the following original papers relating to chemistry and allied sciences:—

What is Good Gas?—Dr. Schilling.—In a lengthy and exhaustive paper, the author reviews this question on all sides, and comes to the following conclusions. A good and suitable gas for artificial illumination ought to possess the following qualities:—(1) The gas ought to possess a normal illuminating power. The exact determination of the value of the normal illuminating power can only be obtained when the gas made from various qualities of coal, and manufactured according to rational principles, is compared, under exactly identical conditions, with the normal standard candle. Any gas which, by a combustion of 5 cubic feet per hour, exhibits a light equal to fifteen spermaceti candles, may be considered a gas of good illuminating power. (2) The gas should be absolutely free from sulphuretted hydrogen. (3) The pressure of the gas at the works and in the leading mains should, as a minimum, amount to from 0·8 to 1·0 of the water-pressure guage.

Researches on the Coals from Saarbrück.—M. Gasch.—A most valuable addition to the chemistry and technology of coals, containing the results of elementary organic analysis, the quantity and quality of gas and coke yielded by each kind of coal, the transportability of the coal (*i.e.*, the resistance against breakage and falling into smalls and dust), carefully determined. The value of coal and coke as fuel, and the exact determination of the illuminating power and durability of the gas, when manufactured on the large scale, according to the best method, including pyrometrical measurement of heat applied to the retorts.

Gas Meter Testing Regulations for the North German Confederation.

Hydrogen and Carbonic Oxide Gas.—M. Schinz.—The author proposes the use of a mixture of equal quantities, by bulk, of these gases, instead of hydrogen only, for illuminating purposes, by means of incandescent platinum. Experiments made prove that the illuminating power of this mixture is, for equal consumption, equal to 1·242, coal gas of good quality being 1·0.

Photometrical Studies.—Dr. Rüdorff.

Contribution to the Purifying Question.—M. Cox.—Under this title, the author discusses and elucidates, by a series of experiments, the action of sulphuretted hydrogen and hydrated peroxide of iron.

Comparison of Various Kinds of Gas in reference to its Cost of Production and Illuminating Power.—M. Sautter.

Zeitschrift für Chemie von Beilstein, No. 21, 1869.

This number contains the following original papers:—

Formation of Glycolamidic Acids.—M. Ziegler.—When a concentrated solution of glycocol and monochloro-acetic acid is boiled with chlorinated diglycolamidic acid, the result is triglycolamidic acid; but since, when glycolic acid and ammonia are boiled with the same substances, neither glycol, nor di- and triglycolamidic acid are formed, the author thinks there is no doubt that, when these acids are prepared from ammonia and monochloro-acetic acid, the one is formed after the other, because an atom of hydrogen bound to one of nitrogen combines with an atom of chlorine of the monochloro-acetic acid.

New Mode of the Formation of a Triphenyl-Guanidine.—MM. Merz and Weith.—Equal molecular quantities of aniline, carbanilide, and one-third molecule of trichloride of phosphorus, yield, when mixed, a solid mass, which, while fusing at 140°, effervesces strongly, and, giving off hydrochloric acid, is converted into a basic substance and phosphorous acid (when carbanilide and aniline alone are heated together to about 190°, no reaction takes place). The basic substance just alluded to is, after having been purified, found to be triphenyl-guanidine, fusing at 143°; its platinum compound contains 19·85 to 20·01 per cent metal. This reaction is represented by the following formula:—

$$\left.\begin{array}{l} N\langle^{C_6H_5}_{H} \\ | \\ 3CO \\ | \\ N\langle^{H}_{C_6H_5} \end{array}\right\} + 3C_6H_5.NH_2PCl_2 = \left\{\begin{array}{l} N\langle^{C_6H_5}_{H} \\ | \\ 3C = NC_6H_5 + 3HCl + H_2PO_3. \\ | \\ N\langle^{H}_{C_6H_5} \end{array}\right.$$

100 parts of carbanilide yield 135·3 parts of this basic substance.

Decomposition of Dichlorobromo-Hydrine by Hydrate of Baryta.—M. Claus.—This paper may be briefly summarised in the following words:—It appears that a dispute has arisen between the author and some other scientific chemists, on the subject of the action of baryta and dichlorobromo-hydrine. Among the products of decomposition, propyl-phycitic acid was found by some of the parties; the author now says that that acid is only glycerinic acid and quadriacid-propyl-phycitic alcohol, formerly supposed by the author to exist, has not had its existence proved with sufficient accuracy.

NOTES AND QUERIES.

Glue and Gelatine.—I would feel obliged if any one would refer me to the memoirs which have been published on glue and gelatine or to any special source of information on these subjects.—G. G.

Utilisation of Sulphate of Lime.—Will any of your readers, through your columns, kindly inform me of some process, or some book which treats of such process, by which the sulphate of lime obtained in neutralising the superfluous acid when making Glauber's salt, can be turned into manure or any other saleable article.—GLAUBER.

Gas and Oil Furnaces.—Your correspondent ("Runcorn") I think, would find creosote do for his purpose; it is used by the Government for melting metal, &c., at Woolwich. The heavy tar oil is burnt in contact with steam, perfect combustion thereby taking place. Should he address himself to me at the Post Office, near Mark Lane, Fenchurch Street, I would give him the necessary information.—R.

Testing Lemon-Juice.—I wish to know what process is followed by analytical chemists in testing concentrated lemon-juice as used by calico printers—viz., to ascertain quantity of citric, tartaric, sulphate, and oxalic acids, chlorides, iron, or any other contaminations contained therein—and should feel obliged if you would, through the medium of your valuable paper, give me the name of some work where I could meet with the information.—A. S.

Bronze for Leather.—Can any of your readers give me the composition of the dye used in giving a rich reddish brown metallic (bronze) appearance to leather? It is altogether a vegetable dye—or, at least, it is either animal or vegetable—because it leaves no residue on combustion. Your correspondent refers to the bronze now so general on ladies' boots and shoes.—A CONSTANT READER.

Reducing the Metal from Impure Chloride of Zinc.—(Reply to "An Old Subscriber.")—Not having stated what are the impurities, it is somewhat difficult to advise on the subject, but perhaps the following plan will answer:—Make a moderately strong aqueous solution of the chloride; add powdered dry chalk in a very slight excess. You thus obtain carbonate of zinc, while chloride of calcium will be in solution. Wash the carbonate of zinc, dry it, and mix it with powdered charcoal and some crude oil, taking care to have excess, by weight, of the former of these substances. Place this mixture in a fire-clay retort, or apply the well-known English zinc-melting method. You will require a very strong heat. The zinc, being a volatile metal, will distil.

Acacia Charcoal.—Japanese Fireworks.—Acacia charcoal is now given as a medicine, sold at a high price, the vendors averring that acacia charcoal, and acacia charcoal alone, is the only efficacious material; in fact, that no other charcoal "need apply." I doubt this. Will any of your chemico-medical readers kindly give me information, or an opinion on the subject.—The pretty little Japanese fireworks, for which I sent you a formula once upon a time, have frequently failed in the hands of my friends. I find the cause to be the enormous degree of adulteration in the flour sulphur; crystallise this from benzol, and all goes well; in this case, an additional part of sulphur is required. Roll brimstone would probably be pure enough. —R. TREVOR CLARKE.

MEETINGS FOR THE WEEK.

MONDAY, Dec. 13th.—Royal Geographical, 8.30.
—— Medical, 8.
—— London Institution, 4.
TUESDAY, 14th.—Photographic, 8.
WEDNESDAY, 15th.—Society of Arts, 8.
THURSDAY, 16th.—London Institution, 7.30.
—— Royal, 8.30.
—— Chemical, 8.
—— Zoological, 4.
FRIDAY, 17th.—Quekett Club, 8.
—— Royal Institution, 8.

TO CORRESPONDENTS.

John A. R. Newlands, F.C.S.—Declined, with thanks. Such purely theoretical speculations occupy more space than we can now spare.

C. R. C. Tichborne.—Received, with thanks.

A Subscriber.—A work on the subject is in the press. It will be announced in these columns.

BOOKS RECEIVED.

The Chemistry of Silesian Sugar-Beets. By Dr. Augustus Voelcker. London: W. Clowes and Sons.

The Life and Letters of Faraday. With portrait and woodcuts. By Dr. Bence Jones, F.R.S., &c. London: Longmans and Co.

The Mechanic. Part 21, for December.

A Manual of Diet for the Invalid and Dyspeptic, with a Few Hints on Nursing. By Duncan Turner. London: John Churchill and Sons.

The Development of the Idea of Chemical Composition. By Alexander Crum Brown, M.D., D.Sc. Edinburgh: Edmonston and Douglas.

Just published, demy 8vo., price 6d.

On English and Foreign Alkalimetrical and Chlorimetrical Degrees, by John Pattinson, F.C.S. Read before the Newcastle Chemical Society.

London: CHEMICAL NEWS Office, Boy Court, Ludgate Hill, E.C.

The Mysteries of Udolpho.—Astounding Effects!! Innumerable Ghosts appear and disappear!! Three emanate from One!! The Scenes by Fid. Beetles crawl the Dungeon.—Occasionally, AMSTERDAM and its EXHIBITION, visited by Professor Pepper.—PECULIAR PEOPLE OF THE PERIOD, By Messrs. Wardroper.—ACCREDITED RELICS of the late MAXIMILIAN. The GREAT LIGHTNING INDUCTORIUM is being increased in power: the wonder of the age and science.—THE MYSTERIOUS HAND.—PETIT CONCERT, introducing Herr Angyalphi, the justly renowned Basso Profundo, the Misses Campbell, and Herr Schalkenbach on the Electric Organ. —ROYAL POLYTECHNIC.—One Shilling.

In 2 vols., 8vo., with Portrait and Woodcuts, price 28s.

The Life and Letters of Faraday.—By Dr. BENCE JONES, Secretary of the Royal Institution.

London: Longmans, Green, and Co., Paternoster Row.

Just ready, Fifth Edition, post 8vo., cloth.

A Manual of Qualitative Analysis. By Robert GALLOWAY, F.C.S., Professor of Applied Chemistry, Royal College of Science for Ireland.

The author has made this edition a more complete work on Practical Chemistry by describing, in addition to the ordinary reactions, other properties of the metals and their oxides, of the acids and salts; and at the end of each group, and each important division of the work, a series of examination questions on Practical Chemistry have been added. Many of the questions are of an entirely new character. Bunsen's flame reactions, and other new analytical methods, have been added.

John Churchill and Sons, New Burlington Street.

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.

Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.

Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash; Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations.

Aluminium and Sodium; Stannates, Fungates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax; Nitre: Gun-Powder; Gun Cotton.

Vol. I., Part 5, price 36s.

Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

Vol. II., price 21s.

Glass, Clay, and Limes.

Vol. III., on Food, Sugar, &c., is at present out of print.

H. BAILLIERE, 219, Regent Street, London.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give Instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

Instruction in Practical Chemistry for Students resident in the South of London.

Dr. JOHN MUTER, M.A.,

Continues to receive Pupils at his Laboratory, whom he instructs in all branches of Practical Chemistry on moderate terms.

Medical and Pharmaceutical Students successfully prepared for their Examinations in a short Course of Evening Lessons. Special Instruction, also, in the Microscopical and Chemical Examination of Articles of Food and Drink.

Every kind of Analysis Carefully and Promptly Executed. Analyses for the Profession at Half Fees.

NEW KENNINGTON INSTITUTE, 289, KENNINGTON ROAD.

Professor Tennant, F.G.S., will deliver a Course of Lectures on MINERALOGY applied to GEOLOGY and the ARTS, at King's College, London, on Wednesday and Friday mornings, at nine o'clock, during October, November, and December commencing October 8th. Fee, £2 2s.

A Course of Lectures on MINERALOGY and GEOLOGY will also be delivered, on Thursday evenings, at eight o'clock. These begin October 14th, and will be continued to Easter, 1870. Fee, £1 11s. 6d. Professor Tennant gives PRIVATE INSTRUCTION in Mineralogy and Geology, Illustrated by a large number of Specimens, at his Residence, 149, Strand, W.C.

THE CHEMICAL NEWS.

VOL. XX. No. 525.

ELECTRICITY IN PLANTS.

By EDWIN SMITH, M.A.

THERE is a very interesting chapter in Becquerel's smaller treatise (in three volumes) on "Electricity and Magnetism" concerning the electrical phenomena of plants. I was induced, by reading this chapter, to make a series of experiments, with a view to illustrate the author's statements, and, if possible, to throw some fresh light upon an obscure and puzzling subject. I am now going to put together some notes of these experiments, carefully made at the time, in the hope that they may not be without a certain interest to others. The galvanometer employed is a home-made one, but tolerably sensitive. My greatest difficulty has been to depolarise the slips of platinum by means of which I have made the voltaic circuits; but every care has been taken, to the best of my ability, to obviate error arising from this cause, as well as from thermo-electric disturbance.

Experiment 1.—Take the thick, juicy leaf-stalk of the common garden rhubarb, and, having cut off a length of from 4 to 18 inches, apply a square of platinum foil to each end of the piece. Connect, by means of platinum wire, these two plates with opposite terminals of the galvanometer. The needle will be powerfully deflected. Now reverse the position of the rhubarb between its platinum surfaces, connect as before, and the needle will again be deflected, but in an opposite direction. Having previously ascertained how to interpret the movements of the needle, by noticing its behaviour when a voltaic current is produced between zinc and diluted acid, with platinum for negative plate, and transmitted through the coil, you will at once conclude that a current of electricity is passing from that end of the leaf-stalk nearest the root towards the opposite end, nearest the blade of the leaf.

Experiment 2.—Cut off a piece about 3 inches long from the thickest part of the same leaf-stalk. Divide it longitudinally down the middle. Pare off a level slice of the outer cuticle. Lay the platinum slips close to the two flat sides thus provided, and connect with the galvanometer. There will be indicated a current from the outer side nearest the cuticle to the inner axis of the leaf-stalk. If the section is made thinner, there will be a current in the same direction. You may confirm your conclusion, as before, by simply turning over the piece of rhubarb, so as to reverse the current. Experiments 1 and 2 may be tried upon a thick midrib or branch of the same, taken from the leaf-blade, with a precisely similar result. A cucumber acts in the same way.

Experiment 3.—Insert a platinum wire into the lower end of the flower-stalk of peony. Apply foil to one of the large bracts, or to a petal; connect, and observe deflection. A current is detected flowing from the lower end of the flower-stalk to the bract or petal. The same experiment may be tried with a sprig of fresh oak-leaves, or bramble, or chickweed, or bunch of elder-buds, or poppy-flower, or stalk and leaves of poppy. The current always sets from the point nearest to the root towards the organs furthest from the root. If wires be inserted in the pistil of a flower and its stalk, there will be shown a current flowing towards the former.

Experiment 4.—Lay a leaf of the common dock between pieces of platinum foil. Connect the different surfaces with opposite terminals of the galvanometer, and notice the deflection. A current is indicated from the upper to the under surface of the leaf. A leaf of Spanish chesnut or of young elder will give the same result; but, in four experiments on a leaf of sycamore, I got a current from the under to the upper surface, after a momentary current in an opposite direction. I infer, however, that the momentary current was the true one, and that the second arose from polarisation; for I obtained this latter current by merely employing filter-paper dipped in distilled water, and laid between the slips of foil.

Experiment 5.—Twist a piece of wire round the outer cuticle of a young twig of hawthorn. Insert a second wire between the bark and wood, so as to touch the layer of cambium. On completing the circuit, a current will be indicated from the cambium to the outer cuticle. Again: pass a wire into the pith, and a current may be detected taking a direction from the cambium to the pith. Instead of hawthorn, a cutting from a fresh branch of elder, laurel, hedge-mustard, thistle, groundsel, yarrow, or other dicotyledonous plant, may be employed, with, as I have uniformly found, the same effect.

Experiment 6.—Scrape off the outer cuticle of the root of cress. By means of wires, as before, test the direction of the electric currents. They will be found to flow from the outside to the axis of the root, and, again, from the root-stock, or point of junction with the stem, towards the lower tapering end. The same effects are exhibited by the root of cat's-ear, or of thistle. If plates of platinum foil are applied to the flat surfaces made by cutting across the thick and thin ends of a carrot, a current will be found to set from the thick end of this root to the smaller end.

Experiment 7.—Take a bunch of the seeds of sycamore. Dip a samara attached to the stalk near its broader end into one of the mercury-cups, and a samara attached to the stalk at a point nearer the smaller end into the other cup. A current is indicated from the former towards the latter, in strict analogy to what happened in the third experiment. Or a piece of the stalk itself may be bent, and its ends dipped into the mercury-cups. A current will be indicated, having the same direction as before. A cutting from any pliable stem may be tried in this way, and always, so far as my experience goes, with a similar result.

Experiment 8.—Pass a platinum wire through the tubular hollow of a stem of *Poa*, or some other meadow-grass. Twist another platinum wire round the outside, and connect both with the galvanometer. A current will be shown, having a direction from the interior to the exterior surface of the stem in question. Such appears to be the law with the stems of monocotyledonous plants.

Experiment 9.—Make two cuts through a raw potato, one through the centre, another near the outer coat. Apply strips of platinum to the two flat surfaces, and connect with opposite terminals of the galvanometer. A current is shown to be passing from the centre towards the outside. A lemon, treated in the same way, furnished a current from the outside towards the centre. With a turnip, a gooseberry, and a pear, the same result was obtained; but a stalk of asparagus followed the law of the potato. A boiled potato, tested, when cold, by the same method, gave a current from the outside towards the centre, the indication being confirmed by a reversal of the slice between the platinum conductors. But, after moistening a fresh piece of boiled potato with distilled water, a current was obtained from the centre towards the outside—a result confirmed by reversing the position of the slice between the platinum conductors, as in the previous trial. Fresh platinum was employed, to obviate, as far as possible, any error from polarisation.

Experiment 10.—Reduce to a pulp with distilled water some of the meal nearest the coat of a baked potato. Then make a similar pulp of some of the meal at the centre. Having placed a plug of tow at the bend of a U-tube, pour the pulps thus prepared into different limbs. Connect, by slips and wires of platinum, with the galvanometer. In my experiment, a current was indicated from the outer pulp towards the inner pulp, agreeably to the result of my first experiment with a slice of boiled potato. My object was to destroy all vitality in the tuber by

boiling or baking, and to see whether any chemical action might still remain—sufficient to cause a voltaic current when meal from different parts of the potato was made to furnish a voltaic couple.

Experiment 11.—Having procured a garden nasturtium growing in a flower-pot, insert a wire in the fleshy stem, a few inches above the soil. Then thrust a second wire through the small hole at the bottom of the pot into the soil. Connect with galvanometer. The needle is so deflected as to indicate the passing of a current from the plant to the soil in which it grows. Watering the soil made no change in the direction of the current when I performed the experiment. I also stuck the first wire into the stem in various ways and in various parts, always with the same results. At the same time, a current was detected passing from the root end towards the leaf end of the stem, conformably to the rule in other cases.

Experiment 12.—Make a solution of oxygen in distilled water, also a solution of carbonic acid. Pour them into the different limbs of a U-tube furnished with a plug of tow. Insert platinum slips, and connect with galvanometer. There will be a marked deflection of the needle, showing the passage of an electric current from the oxygen to the carbonic acid. Confirm the result by reversing the platinum connectors.

The foregoing series of experiments are enough to set one thinking; but I feel that it would be premature to reason upon them at present, even with the admirable clue afforded by the treatise of M. Becquerel. I should like to compare, for instance, the electrical phenomena of plants in spring and in autumn, to see how far they are affected by the condition and flow of the sap.* In a future paper, I may, perhaps, be permitted to return to the subject, and attempt some *rationale* of the curious order of facts above-described.

ON THE

ESTIMATION OF IODINE AND BROMINE,

WITH SPECIAL REFERENCE TO THE

ANALYSIS OF KELP.†

By R. R. TATLOCK, F.C.S.

THE methods for the estimation of iodine and bromine in presence of chlorine that have been devised from time to time are exceedingly numerous, but, in many cases, very unsatisfatory. They generally require either extreme skill and nicety on the part of the operator (a very small error in the manipulation seriously affecting the results), or they are so tedious and inapplicable in most ordinary circumstances as to be of little value. These remarks apply specially to methods that have been described for the estimation of iodine in kelp, in which the presence of bromine is either overlooked or ignored, although its existence would render such methods totally inapplicable.

The object of the following note is to describe a method for the determination of iodine, bromine, and chlorine, in presence of each other, which I have followed for many years, and which has been perfectly successful in the analysis of kelp. It is not intended to supersede other methods, but merely to take its place along with them, its simplicity in the hands of indifferently-skilled chemists rendering it suitable for adoption in the manufacturer's laboratory, a quality which will be valued more particularly in Glasgow—the seat of the iodine manufacture; while, in point of accuracy, it leaves nothing to be desired.

The method, like that of Frederick Field (*Chemical Gazette* for 1857, No. 357), is based upon the wide difference between the equivalents of iodine, bromine, and chlorine; but the mode of procedure is totally different from that of Field, and is not open to an objection which Fresenius has taken to that gentleman's process of determing these three elements. It depends upon the displacement of iodine by bromine, and of iodine and bromine by chlorine. I shall proceed to give the method in detail before referring to its application in the analysis of kelp.

1. The solution containing the iodide, bromide, and chloride, preferably in combination with an alkali metal, is divided into three equal portions, or, at any rate, three equal portions of it are drawn off. To the one, solution of silver nitrate is added in excess, to precipitate the whole of the I, Br, and Cl. The fluid is then feebly acidified with pure nitric acid, warmed, and agitated till the precipitate settles. This is collected on a small weighed filter, washed with hot water, dried as far as possible at 212°, removed from the filter, dried perfectly by heating to incipient fusion, and weighed, the weight of the small portion adhering to the filter being added, and the weight of the whole noted as—

$$AgI+AgBr+AgCl.$$

2. Another portion of the solution is transferred to a small basin, and a quantity of pure bromine-water added. The mixture is then carefully evaporated on an open water-bath, more bromine-water being added from time to time, till the escaping vapours no longer turn starch-paper blue on a fresh addition—showing that all the liberated iodine has escaped. To ensure excess, a little more aqua-bromine is added, and the solution evaporated to complete dryness. The dry residue is then drenched with water, and the result heated till again dry: this operation is repeated two or three times, to ensure the complete expulsion of any hydrobromic acid that may have been present in the bromine-water. The residue, which now consists solely of alkaline bromide and chloride, is dissolved in water, silver nitrate added in excess, the solution acidified, and the precipitate collected and weighed in the usual way. It is noted as $AgBr+AgBr+AgCl$.

3. The last portion of the solution is brought into a small basin, and a quantity of strong chlorine-water added, to effect the liberation of the iodine and bromine. The mixture is then evaporated till all colour is gone, and some more chlorine-water added. If the solution remains colourless, the whole of the iodine and bromine has been expelled, and the alkali metal will exist entirely as chloride. The solution is then brought completely to dryness, after which it is evaporated with a few drops of water two or three times, to expel any hydrochloric or hydrobromic acid. The dry residue is dissolved in water, the solution acidified with pure nitric acid, silver nitrate added in excess as before, and the chloride of silver collected as usual. Its weight is noted as—

$$AgCl+AgCl+AgCl.$$

It is obvious that we have now data from which we can calculate the amounts of iodine, bromine, and chlorine present; for, as the equivalent of bromine is less than that of iodine, in the proportion of 80 to 127, the second precipitate, in which the iodine is replaced by bromine, must weigh proportionately less than the first; and, as the equivalent of chlorine is less than that of either iodine or bromine, in the ratio of 35·5 to 127 in the one case, and 80 in the other, the last precipitate must weigh still less than the second, and we can thus, from the observed differences, deduce the exact quantities of the three elements present.

Example:—

1. $AgI+AgBr+AgCl$	weighed	15·57
2. $AgBr+AgBr+AgCl$	,,	14·69
3. $AgCl+AgCl+AgCl$	,,	12·20

Then—

I.		II.		Observed difference.
15·57	−	14·69	=	0·88

Loss for 1 equiv. I.		Observed loss.		1 equiv. I.		I present.
47	:	0·88	::	127	:	2·378

* My experiments were most of them performed last spring.

† Read before the Glasgow Philosophical Society (Chemical Section), December 6th, 1869.

I.		III.		Observed difference.
15·57	−	12·20	=	3·37

But, as a portion of this loss is caused by the replacement of iodine by chlorine, namely,

Equiv. of I.	Loss in replacing 1 equiv. I by Cl.	I found.	Loss accounted for by I present.
127 :	91·5 ::	2·378 :	1·713

Observed loss.	Loss accounted for by I present.	Difference for Br.
3·37	− 1·713	= 1·657

Loss for 1 equiv. Br.	Observed loss on account of Br.	1 equiv. Br.	Br. found.
44·5 :	1·657 ::	80 :	2·978

Then, as the proportion of iodine and bromine are already known, it will be an easy matter to calculate them to iodide and bromide of silver, and deduct their weight from precipitate 1, calculating the remainder (chloride of silver) to chlorine thus:—

I.	AgI.	I present.	AgI.
127 :	235 ::	2·378 :	4·400

And—

Br.	AgBr.	Br. present.	AgBr.
80 :	188 ::	2·978 :	6·998

Then—

AgI	4·400
AgBr	6·998
	11·398

Then—

15·57 − 11·398 = 4·172

Then—

AgCl.	Cl.	AgCl.	Cl.
143·5 :	35·5 ::	4·172 :	1·032

We had, therefore, present in the solution—

Iodine	2·378
Bromine	2·978
Chlorine	1·032

The bromine water may be easily obtained free from chlorine by distilling bromide of potassium in solution with less potassium dichromate than is necessary to expel the whole of the bromine, using, of course, a little hydrochloric acid.

We now come to the application of the above method to the analysis of kelp.

It is quite obvious that this process cannot be directly applied to substances containing I, Br, and Cl, in very different proportions, and consequently it cannot be used for the estimation of these elements in kelp immediately. The following method of treatment will be found to equalise as nearly as necessary the proportions of the three:—

2000 grs. of the kelp are digested in hot water, the solution allowed to settle, and the clear liquor filtered. The residue is boiled two or three times with water, the fluid being filtered in each case, and the residue finally brought on a filter and washed with boiling water. The filtrates and washings are neutralised as nearly as possible with hydrochloric acid, and chlorine gas passed into the solution till the latter becomes of a distinct orange colour, due to the liberation of iodine and bromine.

The fluid is then shaken up with about one-fourth of its bulk of carbonic sulphide, which takes up the liberated iodine and bromine, and carries them in solution to the bottom of the vessel, provided the specific gravity of the kelp solution be not higher than that of the carbonic sulphide. When this is not the case, the solution of kelp may be diluted till the carbonic sulphide sinks.

The bottom fluid, containing the iodine and bromine, is then drawn off by a fine syphon, and shaken up with an equal volume of water and some zinc-filings. The solution is soon decolourised, on account of the formation of zinc iodide and zinc bromide, which pass into the water; and we have thus a watery solution of the two latter salts above, and colourless carbonic sulphide at the bottom. The latter is drawn off by a syphon, and restored to the kelp solution, to which some more chlorine-water is added; and, if a further quantity of iodine and bromine be liberated, the above operations are repeated till the liquor is quite exhausted.

It only now remains to evaporate the solution of zinc salts, divide into three equal portions, and determine I, Br, and Cl as before described.

With regard to the accuracy of the above method, it may be stated that two sets of trials on pure salts gave the following results, 5 grs. of each of the compounds being used in each case:—

Five grs. KI, 5 grs. KBr, and 5 grs. KCl gave—

	grains.
KI	4·97
KBr	4·97
KCl	5·08

Another trial, with the same quantities, gave—

KI	4·96
KBr	4·95
KCl	5·09

These results leave little doubt that the process is accurate and trustworthy, although I do not deny that other experiments are required to establish the method.

ON MICROSCOPICAL MANIPULATION.*

By W. T. SUFFOLK, F.R.M.S.

(Continued from p. 267.)

In the old microscopes, constructed before the introduction of the achromatic principle, the want of light was very evident when any but the lowest powers were used; this soon led to the employment of some means of increasing the intensity of the illumination. The usual plan was to place a lens beneath the stage, which acted like a burning-glass, and allowed the light to be increased to almost any extent. When the microscopic object-glass was freed from the chromatic and spherical aberrations, the increase of illumination following the enlargement of its angle of aperture for a time satisfied observers; soon, however, a larger amount of light was, in some cases, found desirable, and it was usual to employ one of the object-glasses (generally the next lowest to the one in use) to concentrate the light upon the object. This simple contrivance is very effective when nothing else but greater intensity is needed, and a foreign ¼ object-glass will make a very good combination for this purpose when suitably mounted. For the next improvement, we are indebted to Mr. Gillett, who added a series of diaphragms; these, in the most improved form, comprised some having marginal as well as central apertures, as it was soon found that the direction of the light had a very important influence. The condenser has since undergone many improvements, each of the three leading opticians modifying it to suit the requirements of their respective instruments. It consists, as now made, essentially of a combination of achromatic lenses closely resembling an object-glass, and fitted with one or more diaphragm plates, which, either separately or in combination, give perfect control over the amount of light admitted and its direction; the details of construction vary

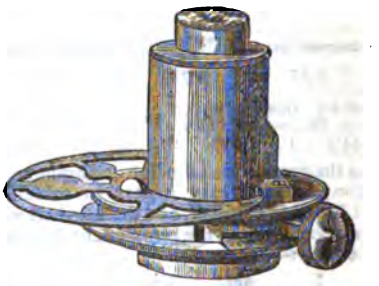
* The substance of a course of lectures delivered to the members of the Quekett Microscopical Club, January—April, 1869.

somewhat in different condensers. This is mounted beneath the stage of the microscope with suitable adjustments for focussing, and also for placing it truly in the axis of the instrument, or centering. As the instrument is difficult for the beginner to use, it is well to give a few directions.

The first care will be to centre the condenser, as the spot of condensed light is extremely small, and, should the adjustment not be accurately made, the field of the microscope will be only partially, or not at all, illuminated. The simplest way of centering is to screw on a very low power, and view the setting of the top lens of the condenser; it will then be readily seen whether it occupies the centre of the field, and, should it not do so, the requisite traversing screws are moved until it is found to be accurately in the centre. Or the image of a lamp-flame may be formed with the condenser, and viewed with a moderately-low power, and the screws moved until the image occupies the centre of the field. The focus is then to be adjusted by moving the milled head connected with the proper rack, and a suitable diaphragm turned into place. When the achromatic condenser is used, the flat mirror is to be employed, and if a lamp is the source of light, the rays must be rendered parallel, as before mentioned. Some observers use a prism in the place of a mirror, as it reflects more light, and of a purer quality, than a silvered glass, which gives a reflection from its upper as well as its silvered lower surface, which is likely somewhat to interfere with the perfect illumination of delicate objects. Although the most intense light is obtained when the condenser is accurately in focus, it is sometimes preferable to use the condenser somewhat out of focus; for this, as well as the choice of diaphragms, no particular directions can be given, as much depends upon the nature of the object to be viewed, construction of the instrument, and many other circumstances. A little practice, with the help, if attainable, of an experienced microscopist, will be found the best means of mastering the use of this rather difficult instrument. It is an instructive exercise to place a suitable object upon the stage—a Diatom, for instance—and notice the changes in appearance produced by altering the focus of the condenser and using different diaphragms; so varied are the kinds of marking produced on some of the *Diatomaceæ* by changes of illumination, that it would hardly be believed that the object was the same. It is now tolerably certain that the striæ, or lines, whether single or crossed, and the dots, seen on some of these objects, are non-existent, being merely the optical rendering of closely-packed transparent hemispheres. These were observed some years ago by Mr. Wenham, with a 1-50th objective of his own construction, and quite recently by a new and comparatively simple means of illumination discovered by the Rev. J. B. Reade, and described by him in the *Monthly Microscopical Journal* (1869, vol. ii., p. 5). The instrument used is an equilateral triangular prism, which is so adjusted as to reflect an oblique beam of parallel rays. With this illumination, the hemispheres on *Pleurosigma formosum* may be seen with a power so low as a ½, provided the angle of aperture be sufficient. This simple illuminator may probably be of great value for other purposes, besides viewing the surfaces of *Diatomaceæ*; at present however, it has been so short a time in use, that its full capabilities have not been tested.

More recently, a condenser, constructed on a different principle, has been introduced, the optical portion closely resembling the Kellner eye-piece, instead of following the usual pattern, which is derived from the object-glass. This condenser (Fig. 31), now well-known as the "Webster," is a most efficient

Fig. 31.*



instrument, and, from the simplicity of its construction, is capable of being adapted with advantage to small microscopes. The amount of light given by it is considerable, so great that with the full aperture it is almost more than the eye can bear; this excess of light, if it can be considered as a fault, is certainly a good one, as it permits a very extensive use to be made of diaphragms. The graduating diaphragm (Fig. 32)

Fig. 32.*

can be applied to the Webster condenser with the greatest advantage, and its effect is much more marked than when merely used below the stage to control the illuminating pencil from the mirror. The wheel above the graduating diaphragm consists of a series of central and lateral stops, by the use of which a great variety of oblique and dark field illumination can be obtained; the latter far more efficiently than by the use of the ordinary spotted lens. Recently, a revolving carrier for additional diaphragms has been added to this condenser. It consists of a tube sliding into the lower part of the condenser, and provided at its upper extremity with a contrivance for holding a disc of card or thin brass, in which one or more apertures may be cut. By turning the diaphragm-holder round, the oblique pencil may be directed from any azimuth, and the effect on such objects as the *Diatomaceæ* is very marked indeed, the striæ appearing and disappearing as the aperture is moved to, or away from, the proper angle for bringing them out. This contrivance also allows the observer to try any forms of stop he may consider advantageous, as they may be quickly cut out of a piece of blackened card (B. W. Richardson, *Quarterly*

* For these woodcuts we are indebted to Mr. Collins, of Great Titchfield Street

Microscopical Journal, vol. vi., pp. 10, 86). The long focus and large field of the "Webster" render it particularly useful for the general purposes of the student, as it will work into some depth of water, and can be used for illuminating the interior of the troughs so frequently employed in observing living aquatic animals and plants. Although surpassed by the more costly instruments for the most refined description of illumination, it possesses merits peculiarly its own, and no single piece of apparatus can be made to perform so great a variety of offices as this very useful condenser.

The most useful forms of illuminating apparatus have now been described; there are many others, chiefly meant for special purposes—they will be found in the works of Quekett and Carpenter, and the pages of the *Microscopical Quarterly* and *Monthly Journals*, to which the student is referred for descriptions and figures.

(To be continued).

ON THE

CONSTITUTION OF THE COMPOUNDS OF SODIUM.

By J. ALFRED WANKLYN, F.C.S.

Some degree of astonishment was expressed when, having discovered that ethylate of sodium and acetic ether give alcohol and an isomer of butyrate of soda, exhibiting a cleavage into alcohol and acetic acid, I did not follow the usual practice of regarding sodium as monatomic, but formulated the new compound as containing a triatomic metal. One of my chemical friends, who appeared to be unable to contain himself, pointed out to the Chemical Society of Berlin that my new compounds could be represented in the ordinary way, and, in accordance with this notion, formulated them as compounds of sodinated-ethyl, wherein the metal, regarded as monatomic, had replaced an equivalent of the hydrogen which, in union with carbon, constituted ethyl in the original compound.

I will, on the present occasion, adduce a reason which will be regarded as decisive against the ordinary formula. If the new compound were really a salt of sodinated-ethyl, it should admit of the replacement of its sodium by ethyl, and, as the result of such an operation, should give acetate of ethylated-ethyl (*i.e.*, acetate of butyl). Now, nothing of the sort takes place. Iodide of ethyl, which is the proper reagent for effecting such replacements, does not produce iodide of sodium and acetate of butyl when it is made to act on my new isomer of butyrate of soda. Neither does the "absolute ethylate of sodium" (which my Berlin friend would write as hydrate of sodinated-ethyl) produce butylic alcohol by a similar treatment. The absence of such transformations, and the actual course taken by the action of the iodide of ethyl on these substances, are, to my mind, conclusive against the formulæ which my chemical friends wanted me to assign to the new isomers of the sodium salts of the fatty acids.

Furthermore, I am unacquainted with any really cogent reason for assigning to sodium a mono-valent function, even in the common, every-day sodium compounds. As yet, no vapour density determination has been made of any compound of sodium. Some nine or ten years ago, in a paper urging the di-valent nature of zinc and mercury, I pointed out that no metallic chloride, or other metallic compound, had been shown to present only one atom of chlorine or other representative of hydrogen in the standard, two volumes constituting the vapour-unit to which vapour densities are referred. The same remark holds good to-day; and, most probably, when chemists have taken the vapour density of common salt, there will be found two atoms of chlorine in the vappur unit.

The facts of the evolution of hydrogen when sodium acts upon water, of double decompositions taking place between salts of sodium and salts of other metals, are not more in accordance with the view that the metal is monovalent than with other views.

On the other hand, the researches in which I have been engaged have constantly exhibited the polyvalency of sodium. I do not know any chemical compound which shows a greater tendency to enter into double compounds than does absolute ethylate of sodium. With HCl, C_2H_3OCl, H_2S, and C_2H_6O, it forms double compounds. With CO_2, it combines, forming a double compound. With NH_3 and CO, there is no action at all, even at 200° C.—neither combination nor reaction to yield separated products. Iodide of ethyl alone (and even this is a doubtful point) may possibly react without preliminary formation of a double compound.

Now, this constant tendency to form doubles is the criterion of polyvalency. Oxygen was regarded as divalent mainly because there are double oxides of the alcohol radicles and no corresponding double chlorides.

The following is a list of compounds wherein the trivalent character of the metal is apparent:—

1. Double compound of sodium-ethyl and zinc-ethyl .. .. $Na'''\{(ZnC_2H_5)'', C_2H_5, C_2H_5$
2. Sodium-triacetyl .. .. $Na'''\{C_2H_3O, C_2H_3O, C_2H_3O$
3. Absolute ethylate of sodium .. .. $Na'''\{O\}C_2H_4$ H
4. Double compound of absolute ethylate with hydrochloric acid $Na'''\{(OC_2H_5)'', H, Cl$
5. Double compound of absolute ethylate with sulphuretted hydrogen .. .. $Na'''\{(OC_2H_5)'', H, (SH)'$
6. Double compound with chloride of acetyl .. .. $Na'''\{(OC_2H_5)'', C_2H_3O, Cl$
7. Acetate of ethylene-sodium .. .. $Na'''\{O\}C_2H_4$ C_2H_3O
8. Valerianate of ethylene-sodium .. $Na'''\{O\}C_2H_4$ C_5H_9O
9. Benzoate of ethylene-sodium .. $Na'''\{O\}C_2H_4$ C_7H_5O
10. Absolute amylate of sodium .. $Na'''\{O\}C_5H_{10}$ H
11. Acetate of amylene-sodium .. $Na'''\{O\}C_5H_{10}$ C_2H_3O
12. Valerianate of amylene-sodium .. $Na'''\{O\}C_5H_{10}$ C_5H_9O

All of these bodies have been actually obtained, and will be found mentioned in my papers. In order to form an adequate idea of the numerical strength of this material, it should be borne in mind that the examples on the above list have, to a great extent, the character of typical cases. Thus, Nos. 7, 8, 9, 11, and 12 are members of one class whose numbers are very moderately computed at ten thousand. And it should, also, not be forgotten that there has, as yet, been no general movement among chemists in search of double sodium compounds, but that search has been confined to one solitary chemist.

It will be observed that, although I continue to look upon sodium as tri-valent, yet that some alteration has been made in the formulæ of absolute ethylate of sodium, and of the isomers of the sodium-salts of the fatty acid. At first, I wrote—

$$Na''' \begin{cases} (C_2H_4)'' \\ OH \end{cases}$$

now I have transferred the oxygen from the hydrogen to the ethylene, and, in place of regarding sodium as two-thirds saturated with ethylene and one-third with hydroxyl, I now regard sodium as one-third saturated with oxygen, one-third with ethylene, and one-third with hydrogen.

Adopting this modification of the formulæ, the various metamorphoses of the compounds may be exhibited with great simplicity and regularity. In particular, the reaction between iodide of ethyl and acetate of ethylene sodium (at first sight one of formidable complication) becomes regular and intelligible when viewed in the light of the new formulæ; it consists in the production of iodide of sodium, alcohol, and caproate of acetylinated ethyl:—

$$Na''' \left\{ \begin{matrix} OC_2H_4 \\ | \\ (C_2H_3O) \end{matrix} \right\} Na''' \left\{ \begin{matrix} OC_2H_4 \\ | \\ (C_2H_3O) \end{matrix} \right\} + 2C_2H_5I =$$

$$= Na_2I_2 + \left\{ \begin{matrix} C_2H(C_2H_5)_2O \\ | \\ OC_2H_4(O_2H_3C) \end{matrix} \right\} + OC_2H_4H_2.$$

In the above list, sodium has always been written as tri-valent; it is, however, right to add that I am prepared to consider the metal as being five-valent in the double compounds of ethylate of sodium with hydrochloric acid, sulphuretted hydrogen, and chloride of acetyl. I have, on other occasions, contended that sodium is seven-valent in the crystalline compound of the ethylate with three molecules of alcohol. As will be gathered from my various papers on this subject, I regard sodium as never *monovalent*, but as tri-, five-, seven-valent, and perhaps even higher. This paper has been restricted to organic compounds; on another occasion, I propose to exhibit the inorganic compounds of sodium in a new light.

London, December 11th, 1869.

ON SOME

TECHNICAL APPLICATIONS OF THE SPECTRUM MICROSCOPE.*

By H. C. SORBY, F.R.S., &c.

(Continued from p. 280.)

On the Age of Dark Wines.

In order to obtain good results considerable care is required, and after trying several methods I found the most satisfactory was as follows:—I have two experiment cells one inch long, made from stout tube, having an internal diameter of about a quarter of an inch. Both ends are cut square, and one is fastened to a piece of glass like a microscopical object by means of purified gutta percha. This I find a most valuable cement for such purposes, since it resists the action of alcohol, acids, and alkalies. The glass must be heated until the gutta percha is sufficiently soft. One of the tubes is carefully graduated into ten equal parts, and the other left plain. Wine in its natural state is often much too dark coloured to enable us to recognise the effect produced by adding sulphite of soda, when we examine the spectrum of the thickness of one inch. It is, therefore, requisite to dilute it with so much of a mixture of one part of alcohol with three of water that the spectrum of the light which has passed through the experiment cells may show a strong, but by no means complete, absorption of the light in the yellow and in the yellow end of the green. After diluting some of the wine to this extent, and adding so much citric acid that it may have a very strong acid reaction, it should be poured into two test-tubes, powdered sulphite of soda dissolved in one, and the other kept without. Though the sulphite may produce a very considerable change at once, the alteration is not complete for awhile, and therefore it is best to keep the solutions for an hour or two in the tubes, corked up to prevent evaporation. The point to be then determined is, how much less thickness of the diluted wine to which no sulphite has been added will give exactly the same intensity of absorption in the yellow, and in the yellow end of the green, as the thickness of one inch of the same acted on by the sulphite of soda. The ungraduated tube should, therefore, be filled with the latter, and a small piece of thin glass placed on the top, so that the light may pass through exactly one inch in thickness of the liquid, and none run out when the tube is placed in an inclined position on the side stage of the spectrum eye-piece. The diluted wine should then be introduced into the graduated tube, which is placed nearly vertically on the ordinary stage of the microscope, and the depth of the liquid carefully regulated by means of a pipette, so that the intensity of the absorption in the two spectra may be exactly the same in the yellow and in the yellow end of the green. The light must be of the same intensity in both spectra; and, therefore, it is also particularly necessary so to regulate the instrument that the transmitted red rays may be of exactly the same brilliancy. The accuracy of this experiment is limited by the difficulty of recognising when the transmitted and the absorbed rays are equal in both spectra, and by its being difficult to determine the depth of the diluted wine to less than 1-100th of an inch. The actual value of the measurements varies, to some extent, according to the manner in which the experiments are made; and, therefore, I strongly advise any one who may wish to employ this method to prepare for himself a table of the comparative amount of change of wines of various ages.

When sulphite of soda is added to a faded solution of the colouring matter of fresh dark grapes it is changed to a pale orange yellow, which colour is, I believe, due in great measure, to the presence of the same yellow substance as is met with in green grapes, so that the intensity of absorption is reduced to about 1-10th, or from 1·00 to 0·10. In the case of the perfectly new wine prepared by myself, the intensity of absorption was reduced from 1·00 to about 0·22. My experiments with the wines of commerce were chiefly made in April, 1868. The newest port wine that I was able to examine was of the vintage of 1866, and therefore about one year and a half old, and even this contained a good deal of the C colour. I examined several specimens of the same vintages of various older dates, which differed considerably in general colour and character, but when all had been kept for the same time in the casks I did not find any material difference in the general results. From the manner in which the experiments were made, the change produced by adding the sulphite of soda is referred to the amount of the C colour taken as unity; and, assuming that the extent to which the wine has been altered by keeping is the difference between the amount still unchanged and unity, the numbers given indicate the relative changes produced by the slow action of the air, but they can only be looked upon as expressing the rate of one particular kind of change. The following table has been constructed from the whole of my observations, so as to give a good general illustration of the subject.

Column 1 shows the age of the wine in years and the date of the vintage.

Column 2 gives the thickness of the diluted wine without sulphite, which produced the same intensity of absorption as 1·00 inch of that to which the sulphite had been added.

Column 3 shows the difference between the values in column 2, divided by the number of years between each

* Communicated by the author, having been published in the *Quarterly Journal of Microscopical Science*, vol. ix., new series, p. 358.

two, so as to exhibit the amount of change for each year, after the wine had been kept for the various periods:—

I.		II.	III.
0	(Made by myself)	0·22	
1½	(1866)	0·63	0·2700
2½	(1865)	0·70	0·0700
3½	(1864)	0·73	0·0300
4½	(1863)	0·75	0·0200
5½	(1862)	0·76½	0·0150
6½	(1861)	0·78	0·0150
9½	(1858)	0·80	0·0070
16½	(1851)	0·82	0·0030
20½	(1847)	0·83	0·0020
33½	(1834)	0·84	0·0008
47½	(1820)	0·85	0·0007

Since the above table does not refer to wines of even years of age, I subjoin below another derived from it by laying down the results on paper as a curve, and interpolating by careful measurements:—

I.	II.	III.
0	0·220	
1	0·550	0·330
2	0·670	0·120
3	0·720	0·050
4	0·742	0·022
5	0·760	0·017
6	0·772	0·012
7	0·782	0·010
8	0·790	0·007
9	0·795	0·005
10	0·800	0·005

It will thus be seen that the rate at which the B colour changes into C is far more rapid in the case of new wine, when much of it is present, than after the wine has become older; being, in fact, about ten times as rapid in the first year as in the third, and about 100 times as rapid as in the twentieth. On this account, the difference for each year is at first so considerable that wines of different vintages could easily be distinguished; but after about six years, the difference is so small that it would be difficult, or impossible, to determine the age to within a single year. After twenty years, a difference of even ten years does not show any striking contrast, and the age could not, therefore, be determined to nearer than ten years by this process. However, up to six years I think it quite possible to determine the age to within a single year. I took specimens of various ports from the casks, of different ages up to six or seven years, and labelled them in such a manner that I did not know the age of any, but could ascertain it afterwards by reference. I then made the experiments with great care, and found that, by proper attention to the details described above, I could correctly determine the year of vintage of each particular specimen.

As already mentioned, the change of the B colour into the C is most probably the effect of the oxygen of the air, which appears to act slowly through the wood of the cask; but the relative amount of these two colours is also modified by the deposit of crust. When kept in well-corked bottles, the change does not appear to be the same, and goes on far more slowly. I therefore think it would be scarcely possible to ascertain the length of time that the wine had been in bottles, and am inclined to believe that the amount of change observed on adding sulphite of soda corresponds more closely with the time that the wine had been previously kept in the cask. I have especially observed this in the case of Bordeaux and Burgundy wines. Those of this type which I have hitherto examined seem to contain a larger relative amount of the B colour, when a few years old, than ordinary ports, and in this respect agree with the so-called *natural port*; but the rate of change is greater when they are kept for some years, probably owing to their containing a less amount of alcohol. There is also a greater variation in different samples of the same age than I have met with in port wine, which is probably because the amount of alcohol in such wines varies more in proportion to the total quantity.

It appears, therefore, that the natural colour of dark grapes is changed by oxidisation into the somewhat similar colour found in new wines, and that, by still further oxidisation, this is converted into another entirely different colour, which becomes much paler by further oxidisation. The rate at which these changes take place varies according to circumstances, but, other things being equal, it varies according to the time of the action. Much also depends on the deposition of colour in the form of crust, and after a long time the original dark coloured substance is almost entirely lost, and only an amber colour remains in solution, which behaves with reagents precisely like that in sherry wines.

On White Wines.

The colouring matter of white wines appears to be derived from one of those yellow substances, soluble in water, of which there are several of materially different character in the faded leaves of different kinds of plants, as more fully described hereafter when treating on hops. That met with in the orange-coloured leaves of the beech is a good example. The depth of the colour is made nearly ten times as great by the addition of ammonia, and when dissolved in strong sulphuric acid diluted with an equal bulk of water, oxidising reagents first turn it much darker, and then much paler. When, however, kept for some months dissolved in dilute alcohol it turns to a much darker tint, and then the solution, with excess of ammonia, is only twice as dark as when made acid by citric acid. Oxidising reagents added to the solution in sulphuric acid do not make the tint any deeper, and thus it appears as if it had been changed by oxidisation into an entirely different colour. The character of this change agrees with what occurs when the colour of dark grapes is oxidised, as already described; and both are good examples of what appears to be a general law. If not already oxidised, a certain amount of oxidisation causes the absorption to advance towards the red end of the spectrum to an extent varying according to the position of the original absorption, and then a still further oxidisation causes the absorption to recede from the red end to considerably beyond the original position, sometimes so much so that all colour is lost. We might thus say that such substances may occur in an unoxidised, in an oxidised, and in a per-oxidised condition. These and similar facts seem also to show that there is an intimate relation between the chemical changes and the particular rays of light absorbed by such substances; but the discussion of this very interesting question would lead me far away from the more immediate subject of this paper.

On comparing the colour of sherry wine with that produced by the action of the air on a solution in dilute

alcohol of the substance in faded beech leaves soluble in water, I was unable to discover any difference, and hence I think we may conclude that it is formed by the oxidisation of the yellow colour of the grapes; but in some wines it is imperfectly oxidised, and they turn darker when exposed to the air.

(To be continued).

NOTICES OF BOOKS.

The Life and Letters of Faraday. By Dr. Bence Jones, Secretary of the Royal Institution. London: Longmans, Green, and Co. 1870. 2 vols., 8vo., with illustrations.

I.

We all remember the terse and pregnant account of the life of Faraday which appeared last year in the *Proceedings of the Royal Society*, and which was written by Dr. Bence Jones. Here we had the broad outlines and main incidents of Faraday's great career; in the work before us we have the details of the picture, the delicate tintings, and careful finish—we have the details of Faraday's life, together with the more prominent incidents which were before known to us. The present "Life" is almost an autobiography; Faraday's letters are frequently quoted *in extenso*, and his manuscripts and journals have been freely consulted. Dr. Bence Jones had at one time hoped that the journals which Faraday wrote when abroad would have been published separately, when, as he remarks, "some portions of his biography would have been in his own handwriting; but it was thought undesirable to divide the records of the different parts of his life."

The principal facts connected with the life of Faraday have been previously enumerated in this journal and elsewhere; we shall assume, therefore, that it is unnecessary to bring before our readers any specially-connected biography, but shall rather content ourselves with noticing here and there some of the less-known phases of a life which we all admire so profoundly, and all so desire to emulate. The desultory character of this notice, therefore, arises from the belief that we have already in our minds, to a greater or lesser extent, a biography of the greatest natural philosopher of our epoch.

In reading Faraday's first letters to Mr. Abbott, which were written when he was twenty years old (1812), we cannot fail to be impressed, not by the amount of knowledge which he had acquired, so much as by the amount of thought which he had exercised. He had already read largely, and had not confined himself by any means to scientific works, but was evidently well acquainted with many of the classics of English literature. These letters are long, somewhat verbose, and decidedly more turgid in style than his later letters; in fact, we notice as we proceed a gradual assumption of that charming simplicity and clearness in writing which all his later compositions possess. An inflated style is the common error of young writers, and it is more often noticed at one certain period of a career, when the writer has rapidly and almost abnormally, so to speak, acquired learning and a taste for expressing his own ideas, than when it has been more gradually amassed, or to a less degree. Faraday had an early opportunity of lecturing, for he joined the City Philosophical Society in 1813, and it was the duty of each member, in rotation, to deliver a lecture. At this time, also, he was in the habit of meeting a few of his more intimate friends for purposes of mutual improvement; they "met of an evening to read together, and to criticise, correct, and improve each other's pronunciation and construction of language."

Shortly after his engagement at the Royal Institution, Faraday wrote several letters to his friend Abbott, on the subject of lecturing, and the qualifications which a lecturer ought to possess (pp. 70-79); these are well worthy the perusal of all who may be engaged in lecturing or science teaching; we find in them many of the precepts which Faraday followed through life, the observance of which made him the most lucid and elegant lecturer of our day. "A lecturer," he writes, "should endeavour, by all means, to obtain a facility of utterance, and the power of clothing his thoughts and ideas in language smooth and harmonious, and at the same time simple and easy. His periods should be round, not too long or unequal; they should be complete and expressive, conveying clearly the whole of the ideas intended to be conveyed. If they are long, or obscure, or incomplete, they give rise to a degree of labour in the minds of the hearers which quickly causes lassitude, indifference, and even disgust." . . . "A lecturer falls deeply beneath the dignity of his character when he descends so low as to angle for claps, aad asks for commendation. Yet have I seen a lecturer even at this point. I have heard him causelessly condemn his own powers; I have heard him dwell for a length of time on the extreme care and niceness that the experiment he will make requires; I have heard him hope for indulgence when no indulgence was wanted; and I have even heard him declare that the experiment now made cannot fail, from its beauty, its correctness, and its application to gain the approbation of all."

During his travels on the Continent with Sir H. Davy, Faraday appears to have kept a careful journal; and this eighteen months of his life, although at times very distasteful, must have had a great effect on the formation of his mind and character, or rather in hastening or ripening his more prominent characteristics. It was, of course, a matter of much benefit to him (too often forgotten by those who speak of his self-education, without any of those advantages which the educated usually possess, &c.) to be in constant communication with one of the most brilliant and profound chemists in Europe, to work with him and for him, to notice the tone and manner of his thought, his treatment of questions of science, his mode of interrogating nature. It was advantageous to see other countries, study other languages, to examine scientifically, and with such a man as Davy, various natural phenomena and results of former phenomena not presented to us in these Islands. We find him one day working at the compounds of iodine (then recently discovered) in the laboratory of the Jardin des Plantes; on another, making the ascent of Vesuvius; he is now burning diamonds with Cosmo de Medici's great lens, now at a masked ball in a domino, or a spectator of the races in the Corso. During his tour, he appears to have had a good deal of time to himself, although, in certain respects, he did not find his post of amanuensis either a sinecure, or exactly what he expected as regards occupation.

Faraday returned to England in 1815, and now commenced his "early scientific training at the Royal Institution." He gave seven lectures during the year at the City Philosophical Society, on various subjects connected with chemistry, and he published his first paper ("An Analysis of Native Caustic Lime") in the *Quarterly Journal of Science*. In concluding his fifth lecture, he says:—"The philosopher should be a man willing to listen to every suggestion, but determined to judge for himself. He should not be biassed by appearances, have no favourite hypothesis, be of no school, and, in doctrine, have no master. He should not be a respecter of persons, but of things. Truth should be his primary object. If to these qualities be added industry, he may, indeed, hope to walk within the veil of the temple of Nature."

Five years later, Faraday, who was then in his twenty-ninth year, commenced what Dr. Bence Jones has well called his "higher scientific education at the Royal Institution." He had for seven years been the private assistant of Davy, and assistant in the laboratory and lecture-room. He had lectured with much success, both in the matter of speech and of experiment, and he had published thirty-seven notices and papers in the *Quarterly Journal of Science*. Yet, with all this, he did not publish the first

of his "Experimental Researches on Electricity" for eleven years from this date; and this period between the end of his first seven years of science-study and the commencement of the publication of these great researches was the time of his higher education in science. Faraday had for many years kept a common-place book. In 1822, he commenced a new and more detail note-book, which he called, "Chemical Notes, Hints, Suggestions, and Objects of Pursuit." In this, we find mention of many researches, which were elaborated and published at a later date. For instance:—

"General effects of compression, either in condensing gases or producing solutions, or even giving combinations at low temperatures. . . .

"State of electricity in the interior and on the surface of conductors, and on the surface of holes through them.

"Transparency of metals. Sun's light through gold-leaf. Two gold leaves made poles—light passed through one to the other."

At a later date, he wrote at the commencement of this collection of notes—"I already owe much to these notes, and think such a collection worth the making by every scientific man. I am sure none would think the trouble lost after a year's experience."

In 1823, Faraday was elected a Fellow of the Royal Society; and other scientific honours now began to be offered him. He received, altogether, ninety-five honorary titles; and of these he said:—"One title—namely, that of F.R.S.—was sought and paid for; all the rest were spontaneous offerings of kindness and goodwill from the bodies named."

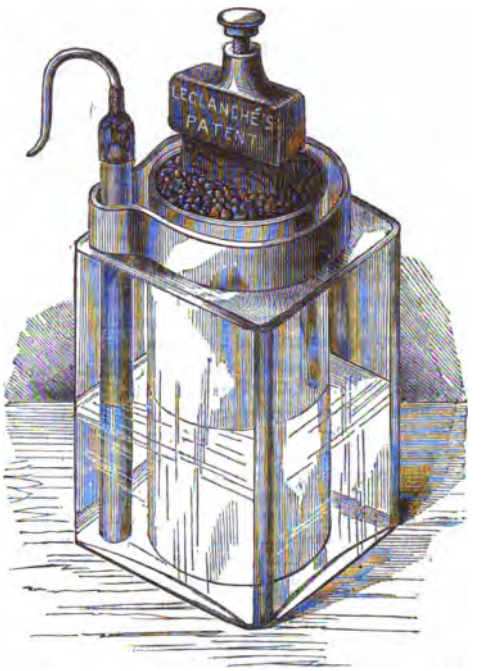
In 1825, on the recommendation of Sir H. Davy, Faraday was appointed Director of the Laboratory of the Royal Institution; and one of his first acts was to invite members of the Institution to attend evening meetings in the Laboratory, at which Faraday showed new and striking experiments. From these meetings sprang the Friday evening discourses so well known to all of us, and the establishment of which probably, remarks Dr. Bence Jones, "saved the Institution."

Let us, now that we have arrived at the last year (1839) of Faraday's higher scientific education, pass in review some of his work, before passing to the commencement of that great series of researches which numbered more than fifteen thousand paragraphs, and was concluded in 1856.

He had already made notable researches on electro-magnetic motions, on the condensation of gases, on the manufacture of glass for optic purposes, and on the alloys of steel. He had discovered two chlorides of carbon, benzol and sulpho-naphthalic acid; and he had made various experiments on the diffusion of gases. Moreover, he had published sixty scientific papers, nine of which were in the *Philosophical Transactions*. Here, then, for the present, we will leave him, in his thirty-ninth year.

Treatise on the Leclanché Battery: Preceded by a Few Remarks on the Employment of Electrical Batteries in Telegraphy. London: The India Rubber, Gutta-Percha, and Telegraph Works Co., Silvertown, Essex, and 100, Cannon Street, London.

IN this pamphlet will be found a full description of the Leclanché cell, the main feature of which is that peroxide of manganese is used with zinc (amalgamated) and an aqueous solution of an alkaline salt, chloride of ammonium being preferred. The author states, and his statement is borne out by comparative experiments made with the Marié-Davy, Daniell, and Bunsen cells, that the Leclanché cell is preferable to any other. The cells are of three sizes, and the shape is shown in the accompanying cut; the smallest, with a porous pot 4·3 inches high, can accomplish an annual electric work which may be represented by 62 grains of copper reduced in the voltameter; the medium size, with a 6-inch porous pot, can reduce from 950 to 1000 grains, while the large size gives a work equal to 1500 or 2000 grains. We have ourselves tried the cell, and can recommend its use to those



who require galvanic electricity for telegraphic or other purposes.

CORRESPONDENCE.

THE METEORIC IRON OF DEESA.

To the Editor of the Chemical News.

SIR,—I find in the CHEMICAL NEWS (vol. xx., p. 274) an abstract of the memoir published by *Cosmos* concerning the meteoric iron of Deesa.

Allow me to observe that the results indicated (except those which relate to the elementary composition of the metallic part) have not been obtained by M. Domeyko, but by myself.

I will add that the examination of the Deesa mass has led me to considerations which I believe to be new on the origin of meteorites.

The characters offered by this mass are such that it is impossible not to perceive in it a specimen of the first *meteoric eruptive rock* hitherto observed.

Consequently, the meteorite mass of Deesa permits us to affirm that meteorites, anciently in *statographical relations*, come from a globe, now broken up, which formerly revolved round the earth.

Finally, the consideration of *meteoric dykes* gives us the relative geological age of meteorites.

I shall be very glad if this letter can find a place in your most valuable journal.—I am, &c.,

STANISLAS MEUNIER,
Docteur ès Sciences,
Aide Naturaliste au Muséum.
23, Rue de Vaugirard, à Paris, Dec. 4th, 1869.

PHOSPHAMIDES.

To the Editor of the Chemical News.

SIR,—In your last number, among the "Chemical Notices from Foreign Sources," is an abstract of a paper by Schiff,

in Beilstein's *Zeitschrift für Chemie*. In that paper he comments on one of mine, and re-asserts the existence of phosphotriamide, $P(NH_2)_3O$; but it is evident that his acquaintance with my communications to the Chemical Society on the various phosphamides is imperfect, and a statement of the different results of our experimenting may not be without its value.

Schiff's statement is that ammonia gas, passed over oxychloride of phosphorus, is capable of eliminating the whole of the chlorine, producing a triamide, thus:—

$$PCl_3O+6NH_3=P(NH_2)_3O+3NH_4Cl;$$

and that this triamide may be separated from the chloride of ammonium by means of water, in which it is insoluble.

My statement is that I have never succeeded in replacing more than two equivalents of chlorine at any temperature, and that the amidated oxychloride thus produced is at once decomposed by water with the formation of pyrophospho-triamic acid, thus:—

$$PCl_3O+4NH_3=PCl(NH_2)_2O+2NH_4Cl, \text{ and}$$
$$2(PCl(NH_2)_2O)+2H_2O=P_2(NH_2)_3HO_4+NH_4Cl+HCl.$$

But, where a high temperature has been employed in saturating the oxychloride with ammonia, the product of the action of water is not the -triamic acid, but what I have called pyrophospho-pentazotic acid, $P_4N_5H_9O_7$.

Schiff's original view rested mainly on one determination of phosphorus and nitrogen in his supposed phosphotriamide, which, however, gave numbers not very accordant with theory, while the phosphorus is nearly the same under either view. In his present note, he rests rather on the fact that the white powder, when heated *per se*, gives off ammonia without any chloride of ammonium, leaving PNO, and losing 36 per cent in weight.

My view rests on a large number of analyses of the two acids and their salts, and on the fact that, in my experiments, the oxychloride of phosphorus could never be made to increase in weight by the absorption of ammonia more than about 44 per cent, while a complete replacement of the chlorine would give 66·3.

It is evident that, under either view, ammonia without any chlorine must be given off when the white substance is strongly heated, and that phosphonitryl, PNO, is a probable result. I have already stated that pyrophosphotriamic acid, heated at low redness, gives off about 10 per cent of ammonia; and in an experiment, made for the purpose of determining how great a loss the substance would suffer when strongly heated, 16·85 per cent was all that could be obtained, and the black fused mass that remained in the tube was not pure phosphonitryl.

That Schiff should obtain a loss of 36 per cent would seem to indicate that he has produced some different compound from any of the acid amides, the formation of which has been my invariable experience.—I am, &c.,

J. H. Gladstone.

17, Pembridge Square,
Dec. 9, 1869.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the Chemical News, *with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."*

Note. All degrees of temperature are Centigrade, unless otherwise expressed.

Bulletin de l'Académie Impériale des Sciences de St. Petersbourg, Vol. xiv., No. 2, 1869.

The only paper relating to chemistry in this number is:—

Absorption of Hydrogenium by Iron Galvanically Obtained.—M. Jacobi.—Iron, precipitated galvanically, is described by the author as a silver-grey coloured, velvety-looking, very finely-grained mass, of 7·675 sp. gr. at 15°; this metal is so hard that it scratches glass, but is, also, very brittle. When this metal was very carefully ignited in a covered platinum crucible, its colour became deeper, its hardness and brittleness were lost, and its sp. gr. had increased to 7·811, which is higher than that of wrought-iron. The fact of this increase of specific gravity led the author to conclude that the iron might contain gas absorbed in its substance. A quantity of 9730 grms. were treated in a Sprengel's aspirator, with the result that, aided by an increased temperature, which was carried to dull-red heat, 1776 volumes of gas, chiefly composed of hydrogen, were obtained from the quantity of iron submitted to experiment.

Les Mondes, November 25, 1869.

This number contains the following original matter:—

Speech at the Opening Meeting of the German Naturalists and Physicists, at Insprück.—Dr. Helmholtz.—From this very eloquent and very able speech, we quote the few following phrases:—The discovery of the common tie existing between and uniting together all the phenomena of nature, is the final aim of all science, and towards the reaching of that aim the efforts of all workers of science must be directed; only the knowledge of the laws which rule and govern the material world will enable man to make it obey his will. The speaker, in his discourse, referred briefly to astronomy, as the science of the laws of gravitation; to chemistry, as the science of inalterability of matter and its varied combinations; and next spoke about conservation of forces. At the conclusion, the speaker stated that Germany is, therefore, in advance of all the rest of the scientific world; because, out of that country, and more especially in France and England, scientific men had to heed social, and, far more yet, religious prejudices, and were thereby prevented free utterance of thought, since it would damage their social influence. On the whole, the speech is thoroughly Teutonic in the highest sense of the word, and the terseness, as well as the eloquence of the printed report, cannot fail to imbue the reader with respect for the very sound and able manner wherewith the eminent speaker discussed, extempore, abstruse scientific truths. Under the presidency of Prof. Hlasiwetz, of Vienna, the following papers were read in the chemical section:—(1) On "Iodoform," M. Lieben; (2) "On Lactic Acid," M. Wislicenus; (3) "On Phenylic Brown," M. Rolly; (4) "On Proteine Substances," M. Schwartzenbach; (5) "On the Sulphurets of Nitrogen," M. Claust; (6) "On the Hydruret of Palladium," M. Boettger; (7) "On Anthracen," M. Petersen; (8) "On Hydrargyrodinaphthyl and Phenyl," M. Otto.

Presence of Salt in Sea Air.—Dr. Gillebert d'Hercourt.—From a series of observations made at Monaco, on the shores of the Mediterranean, the author concludes that there is always on the sea shores an atmosphere impregnated with saline particles; this layer of air has, at the above-named place, some 500 metres' horizontal, and some 60 metres' vertical extent. This impregnation of salt is due to what the author terms "pulverisation" of the sea-water by the breaking-up of the surf, and is not directly influenced either by barometric pressure, hygrometric state of the atmosphere, or its temperature. This hydro-mineral dust (*poussière*), as it is called by the author, is, unless there happen to exist near the coast physical obstacles, in the shape of high mountains, carried far away inland, and is not to be confounded with what is of more coarse nature, and termed "spray," which is only quite local, and produced when a gale of wind blows. The author states that, even on calm days in winter, the atmosphere near Monaco is at least up to a height of 70 metres, and some few miles inland impregnated with this hydro-mineral dust. There is no tide (rise or fall of water) perceptible in the sea alluded to.

Journal de Pharmacie et de Chimie, November, 1869.

This number contains the following original papers:—

Researches on the Bleaching of Tissues.—M. Kolb.—The second portion of a lengthy paper on this subject.

On Carlinate of Potassa and Carlinic Acid.—M. Lefranc.—Carlinate of potassa is a white-coloured salt, crystallising in needle-shaped crystals, and soluble in water and in alcohol of 60 per cent. When it is carefully heated, it fuses in its water of crystallisation; and when the heat is increased, it burns off, leaving carbonate of potassa. The aqueous solution of this salt gives no precipitate with chloride of barium, and with neutral or basic acetate of lead; with nitrate of silver it yields a white precipitate, insoluble in acetic, but soluble in nitric acid. The carlinic acid is separated from any concentrated aqueous solution of a carlinate, by means of a slight excess of tartaric acid. Alcohol is added in excess, the fluid filtered, and next evaporated upon a water-bath to dryness, and taken up with ether, from which the acid separates, on evaporation, in a crystalline shape. The acid is very soluble in water, alcohol, and ether, and is naturally met with in the roots of the *Carlina gummifera*, L.

Best Method of Preparation of Emetics.—M. Fleury.—This is a short memoir, not as would be inferred from its title, on the preparation of the potassio tartrate of antimony, but on the preparation of a series of double salts of tartaric acid and bismuth with lime, baryta, magnesia, protoxide of manganese, oxides of copper and zinc; of tartaric acid with chromium, lime, and baryta, and similar salts of iron. The author promises to give, in a future paper, the mode of preparation and analysis of all these salts.

On Chloral.—M. Poggiale.—The contents of this paper are superseded by the paper on this subject abstracted by us from the *Berichte der Deutschen Chemischen Gesellschaft zu Berlin*, No. 16, 1869.

Camphor Water.—M. Jeannel.—The question of the solubility of camphor in water has been often discussed. According to the author, an alcoholic solution of camphor was made containing 0·375 grm. per c.c.; and a litre of water at 15° does not dissolve more than 0·75 grm. of camphor from this solution after twenty-four hours' contact and frequent shaking. The author states that alcohol does not increase perceptibly the solubility of camphor in water; alcohol at 20° only dissolves 2·437 grms. of camphor, and at 35°, 6 grms. of that substance per litre of alcohol.

Explosion Caused by the Incautious Making-Up of a Medicinal Prescription.—M. Vigla.—The following prescription was handed to a pharmaceutist:—Chlorate of potassa, 8; hypophosphite of soda, 4; simple syrup, 62; water, 125. The operator put the dry salts in a mortar, and commenced rubbing them vigorously, when a most violent explosion ensued, whereby the mortar was smashed to atoms and the operator seriously wounded. The proper course would have been to dissolve each of the salts separately in water.

Moniteur Scientifique, December 1, 1869.

This number contains the following original papers:—

The Physical Phenomena Manifested by Living Organised Beings.—M. Gavarret.—In a lengthy paper, the author discusses and explains the physico-chemical phenomena of life, as far as this is possible. The paper is recommended to the attention of all who study biology.

Artificial Alizarine made by MM. Meister, Lucius, and Co., at Hoechst.—M. Kopp.—Since this subject is, in a scientific as well as industrial point of view, of great importance, we abstract this paper, notwithstanding the same subject has been lately treated by Dr. Bolley. M. Kopp received, from the well-known chemist, M. C. Kœchlin, a quantity of 250 grms. of this artificial alizarine, in the shape of a paste, containing only 7 per cent of dry substance, ash inclusive. The author states that this substance produces a most brilliant and very fast Turkey red. The artificial alizarine was dissolved in a weak aqueous solution of carbonate of soda, filtered and precipitated by means of pure HCl, and the precipitate collected on a filter until the filtrate was quite neutral; the material, thus purified, was used for the purpose of comparison with pure alizarine as obtained from madder. Equal quantities of each of these two substances were dissolved in a weak solution of caustic soda, and with these solutions the following tests were made:—Artificial alizarine $+Na_2O+Cl_2Ba$: violet-blue precipitate, supernatant liquid somewhat faintly rose-coloured; natural alizarine, and the same reagents; also a violet-blue precipitate, supernatant liquid faintly yellowish-rose coloured. Artificial alizarine $+Na_2O+ClCa$: a violet precipitate, supernatant liquid wine-red coloured; natural alizarine, and ditto reagents, ditto precipitate, supernatant liquid wine-red coloured, but less deeply. Other reactions were instituted, all leading to the manifest conclusion that there is no essential difference between this artificial alizarine and natural alizarine. The author records, at length, his experiments with this artificial alizarine, and the action of nitric acid upon this substance, the result of which is that the substance in question gives rise, not only to the formation of phthalic acid, but also nitro-picric acid. When this dried artificial alizarine is treated, at between 150° and 170°, with boiling petroleum oil, a large proportion of the colouring matter is dissolved, and, on cooling, deposited from the oil in needle-shaped crystals. Dr. Quesneville, the editor of the periodical above quoted, adds to M. Kopp's paper a letter received by him, the main purport of which is that MM. Græbe and Liebermann, at Berlin, have been having, with the firm of Meister, Lucius, and Co., a lengthy correspondence, and have been treating with them for the carrying out of their invention on the large scale. These negotiations do not appear to have been successful; and the head of the firm at Manheim, which now carries on the working of the patent of MM. Græbe and Liebermann, happening to be at Berlin while the negotiations with the firm at Hoechst were still pending, accepted the terms made by MM. Græbe and Liebermann; and there is reason to suppose—and this supposition is strongly cofirmed by the researches made by MM. Kœchlin, Bolley, Alfraise, and Kopp, on the artificial alizarine made at Hoechst—that that substance is, in reality, obtained by the process discovered by MM. Græbe and Liebermann, and not, as it is made to appear, by a peculiar process the invention of the manufacturers.

On Ipecacuanha and Emetine.—M. Lefort.

Use of Alkaline Sulphurets for the Purpose of Bleaching Fibres and Tissues of Vegetable Origin.—M. Tessié du Motay.—The chief point in this paper is that the author supposes that the alternate action of reducing and oxidising substances accelerates the bleaching of hemp, flax, and cotton, and the tissues made thereof, and that the strength of the fibre is less impaired by this process. The substances applied as reducing materials are the sulphides of barium or calcium mixed with some sulphide of sodium, and the oxidising substance is chlorine water.

Revue Hebdomadaire de Chimie, November 25, 1869.

New Kind of Gas Furnace.—MM. Bergé and Delheid.—This furnace, or, better, blast-lamp, is a modification of the Bunsen burners in general use, and differs from the latter in the following particulars:—(1) By the mode of the admission of the air, which is made to come in below the gas, and not on the same level therewith, or above it, as in the ordinary Bunsen burners; (2) by the admission of a larger quantity of air, by making it pass through the entire area of the tube; (3) by the addition of an outer cylinder, placed to prevent the heating of the tube from which the flame issues, by making a current of air pass between the two. From the report of the makers of this apparatus, it appears to be of immense service, especially for fusions of mineral substances requiring a high temperature and long-continued heat.

Mode of Treatment of the Fermented Molasses' Juice in order to Extract therefrom Crude Potassa Salts.—MM. Crespel and Bocquet.—The authors add, to the residue of the distillation of the previously-fermented molasses as obtained from beet-root sugar making, a sufficient quantity of carbonate of baryta to convert the sulphuric acid present therein as sulphates into carbonates, and thus to obtain more carbonate of potassa in the saline residue after calcination. The sulphate of baryta formed hereby is re-converted into carbonate by well-known methods.

Formation of Ellagic Acid by means of Gallic Acid.—M. Lowe.—When an aqueous solution of two equivalents of gallic acid and one equivalent of arsenious acid is boiled for several hours, a crystalline precipitate is formed, which is ellagic acid. When it is desired to prepare the latter in quantity, the mixture of the two substances alluded to is made in the proportions mentioned, and, after having been boiled and evaporated to dryness at 120°, is exhausted with alcohol at 90 per cent, wherein the ellagic acid only is soluble.

December 2, 1869.

Salts of Uranium and Cobalt.—M. Selhorst states that, notwithstanding some assertions made to the contrary, the solutions of salts of uranium and cobalt are not fluorescent in Geissler's tubes.

Chemical Method of Purifying Tissues made of Animal Fibres.—MM. Bang and Monestier.—The authors state that woollen and silken tissues are purified from vegetable fibres accidentally mixed up therewith, by steeping the tissues in a mixture of equal parts of water and strong sulphuric acid at 90° temperature, followed immediately by a very efficient washing in plenty of cold water, best a running stream.

Bleaching Wool and Silk.—M. Frézon.—The author proposes to substitute, for the ordinary sulphuring, as it is termed, the use of a mixture of equal parts, by weight, of oxalic acid and common salt, of each 2 kilos., upon 1000 litres of water. The tissues, or yarn, to be bleached is left in this bath for one hour, and next washed in plenty of fresh water.

Boiling-Point of some Concentrated Solutions of Salts.—M. Legrand.—Upon 100 parts of water, each of the following substances, in the quantities quoted, yields a solution, the boiling-point of which is expressed in °C.:—61·5 of chlorate of potassa, 104·2°; 60·1 of chloride of barium, 104·4°; 48·5 of carbonate of soda, 104·63°; 112·6 of phosphate of soda, 106·6°; 59·4 of chloride of potassium, 108·3°; 41·2 of chloride of sodium, 108·4°; 88·9 of chloride of ammonium, 114·2°; 296·2 of neutral tartrate of potassa, 114·67°; 335·1 of nitrate of potassa, 115·9°; 117·5 of chloride of strontium, 117·85°; 224·8 of nitrate of soda, 121·0°; 209·0 of acetate of soda, 124·37°; 205·0 of carbonate of potassa, 135°; 362·2 of nitrate of lime, 151°; 798·2 of acetate of potassa, 169°; 323 of chloride of calcium, 179·5°; an unlimited quantity of nitrate of ammonia, 180°. All the salts to be applied in dry state.

The Journal of the Franklin Institute, October, 1869.

This number contains the following original papers relating to chemistry and allied sciences:—

Various Processes for Preserving Timber.—Dr. Ott.—From this paper, the second portion of a lengthy memoir on this subject, we learn that the opinion that carbolic acid, and substances containing it, or supposed to contain it, are effectual in preserving timber, is erroneous. The real preservative action of the tar-oils are due, according to this author, to a greenish fluorescent oil that comes over at the last stage of the distillation. Direct trials with pyren and paranaphthaline do not yield successful results. The question whether tar (coal-tar) does contain a sufficient quantity of the fluorescent greenish oil just alluded to, so as to justify the use of coal-tar for preservative purposes, is answered in the negative. The decay of timber, or peculiar transformation which makes it unfit for practical purposes, seems to be, in most instances, produced by the attack of fungi and lichens. The mouldering of wood is distinct from decay, it being merely a chemical process caused by the action of water with small access of air. None of the processes invented to preserve timber by chemicals are perfect; the most simple and practical method is the old, but, unfortunately, far too slow, plan of properly subjecting timber to the action of air and water, as practised in ship-building yards.

This number is almost entirely filled with various valuable papers on the late solar eclipse.

American Journal of Pharmacy, November, 1869.

This number contains the following matter more particularly relating to chemistry:—

Prevention of the Bumping of Liquids.—M. Schumann.—After briefly referring to the several suggestions made for this purpose, and, among these, in particular to Dr. H. Müller's process, the author says—In distilling acids and other liquids, I proceed in the following manner:—The end of an ordinary glass pipe, of about ¼ of an inch opening, is shut at one end, and this end bent into a little hook; the glass pipe is then cut exactly so long as to reach from the bottom of a glass retort to within ¼ or 1 inch of the stopper of the tubulus. By

means of the hook and a piece of twine, or a little hook of thin wire, this glass pipe is placed into the retort, the open end at the bottom, and the retort can be filled, or the retort is filled first and the glass pipe entered afterwards. If the liquid is warmed, the air in the glass tube is expanded, and constantly bubbles out at the open end; and if the boiling-point is reached, vapours of the tension of the atmosphere are formed at the spot where the glass pipe stands on the bottom of the retort, and the boiling continues regularly and quietly.

New Properties and Uses of Naphthaline.—Dr. Ott.—After relating the manufacture of this substance, the author says—Pure naphthaline, as now met in the trade, is similar to alabaster, cracks easily in the warm hands, and becomes negatively electric on being rubbed with silk. Its sp. gr. at 66° F. is 1·15173, melts at 174° F., and boils at 452° F. Molten naphthaline absorbs a large quantity of air, which is given off again on cooling; according to M. Vohl, this gas is pure oxygen. Molten naphthaline dissolves indigo with great facility, forming a dark blue violet liquid, from which the indigo separates on cooling, forming fine shining needles like copper. The amorphous sulphides of arsenic, tin, and antimony are also readily dissolved, and likewise phosphorus, sulphur, iodine, the iodide and chloride of mercury, arsenious, succinic, benzoic, and oxalic acids. Naphthaline can be converted into naphthalic, or phthalic acid, and this latter into benzoic acid, and that, in its turn, into benzol. Naphthaline, $C_{20}H_8$; phthalic acid, $C_{16}H_4O_8$; benzoic acid, $C_{14}H_6O_4$; benzol, $C_{12}H_6$. For the conversion of naphthaline into phthalic acid, 12 parts of pure naphthaline are dissolved in 90 parts of concentrated sulphuric acid, and, next, 80 parts of best finely-powdered peroxide of manganese are added. After the reaction is complete, the product is boiled in five times its own bulk of water, until no more carbonic acid gas is given off; the fluid is next diluted with water, filtered, and evaporated. The conversion of the phthalic acid into benzoate of lime, at a temperature of from 625° to 660 F., is performed in vacuum, but requires considerable skill and practice; an excess of lime is required.

NOTES AND QUERIES.

Testing Lemon-Juice.—"A. S." is referred to O'Neill's "Chemistry of Calico Printing and Dyeing, &c.," page 140 and following pages.

Glue and Gelatine.—(Reply to "G. G.")—See "Knapp's Technology," English edition, by Dr. Richardson and Mr. Watts; see Wagner's "Hand und Lehrbuch der Technologie," vol. v., p. 80 and following pages.

Mellite or Honeystone is a rather rare mineral, consisting of mellitic acid, alumina, and water; its colour is honey-yellow; it occurs in brown coal in Thuringia, near Bilin, Bohemia, and in a few other localities.

Utilisation of Sulphat e of Lime.—(Reply to "Glauber.")—Sulphate of lime, whether it be precipitated, or the native sulphate ground into powder, is useful as a manure by itself. If the article you allude to is very white and pure, it may find a sale among paper makers.

Bronze for Leather.—(Reply to "A Constant Reader.")—It would be impossible to give you the composition of such a substance as you allude to without actually testing the material; but it is very likely that the substance used is a strong alcoholic solution of aniline purple, which is applied for bronzing purposes.

Acacia Charcoal.—(Reply to R. Trevor Clarke.)—This is probably inferior to willow charcoal; the latter makes a very soft smooth powder, and mixes readily with water. The wholesale price varies from 1s. 4d. to 1s. 6d. per lb. Logwood charcoal has been sold under the name of "the immortal carbon."—G. A. K.

Acacia Charcoal.—(Reply to R. Trevor Clarke.)—You are quite correct as to your surmise concerning acacia charcoal; refer to Pereira's "Materia Medica," 4th edition, vol. i., page 320 and following. Wood charcoal obtained from the lime, or linden tree, *Tilia Europea*, L., is officinal in some Pharmacopœias. The cause you suggest of the failure of the use of flowers of sulphur is, we think, wrong; the reason is that, unless flowers of sulphur have been washed, they always contain sulphuric acid. Roll sulphur only is used in the powder manufacture for the same reason.

Analysis of Nitrous Oxide.—Happening to meet with a copy of Roscoe's "Elementary Chemistry," and looking over the article "Nitrous Oxide," I find he asserts that, after analysis of the gas by potassium in a bent tube over mercury, the products, after combustion of the metal in the gas, are nitrogen and potassium hydroxide, KHO! Where does the H come out of? will Professor Roscoe kindly explain this?—VERITAS, Liverpool.

Specific Gravity.—Would you kindly favour me with an answer to the following question:—I read of solutions as being of sp. gr. 1·053, &c. Now what is the rule for determining these strengths by Twaddle's hydrometer; or, in other words, how may I know the rule for calculating these strengths, that when I see the sp. gr. I may calculate them, so as to be able to know at what number of degrees is equal on Twaddle's? I should be glad if you would enlighten me on this point. —CHAS. H. PARKIN.

Electro-Deposition of Copper upon Cast-Iron.—In attempting the above, the writer finds great difficulty in obtaining adhesion between the copper and the rough surface of the cast-iron, previously cleansed by dilute sulphuric acid. Whether the deposit be made slowly or quickly, it is soon separated from the iron by a black powder, which appears to consist chiefly of carbon, silica, &c. Information, or reference to treatises, will be much esteemed by HISTRIX.

Treatment of Oils for Machinery Purposes.—Can any of your readers supply any information upon the process of refining animal and vegetable oils, having special regard to the abstracting the gummy or albuminous matter, without introducing any acids that would be injurious to the machinery afterwards; or perhaps they could recommend some work which treats upon the subject.—B. S.

Gas and Oil Furnaces.—"J. C.," who enquires about gas and oil furnaces, in the CHEMICAL NEWS of September 24th and December 3rd, will find the coke produced in distilling crude anthracene and coal-tar grease from asphaltum to yield him the intense heat he requires, practically free from sulphur and deposit. It could be used in the Siemens regenerative furnace or otherwise.—WM. SCHOFIELD.

MEETINGS FOR THE WEEK.

MONDAY, Dec. 20th.—Medical, 8.

—— Society of Arts, 8. J. Norman Lockyer, F.R.S., "The Spectroscope and its Applications."

—— London Institution, 4. Prof. Guthrie, "Elementary Physics."

WEDNESDAY, 22nd.—Society of Arts, 8. Dr. J. L. W. Thudicum, "On Wines—Their Origin, Nature, Analysis, and Uses; with Special Reference to a New Alcoholic Drink Made from Tea."

ON MICROSCOPICAL MANIPULATION.*

By W. T. SUFFOLK, F.R.M.S.

(Continued from p. 293.)

In the modes of illumination hitherto described, the light has been made use of in exactly the same condition in which it was received from its source, whether from the sun or a lamp. All that instruments have been required to do has been either to alter its direction or, by concentration, to increase its intensity. It is now proposed to explain a method of conducting microscopical investigations in which the properties of the light have undergone such changes as to produce effects totally different from those of ordinary illumination, and with the result of giving greater insight into the nature of certain structures than could be obtained by other means. The light, in the condition now to be described, is commonly known as *Polarised light*.

With a view to simplify the matter contained in the foregoing papers, no more has been said about the nature and properties of light than was absolutely necessary to enable the action of the apparatus described from time to time to be tolerably well understood. And, although, in the present chapter, far more notice must be taken of the subject, it is by no means intended to give an exhaustive account of the phenomena of polarised light. Space can only be afforded for such an outline as will enable the student to use his apparatus, and observe intelligently. For details, reference must be made to works treating more fully on the subject—such as the chapters on Optics in Mr. Brooke's "Manual of Natural Philosophy," and the various authorities there referred to.

Light, in common with the other forces of nature—heat, electricity in its various forms, dynamic force, &c.,—proceeds from its source in a series of undulations or waves, which may be illustrated in a rough manner by throwing a stone into a pond, when the waves will be seen to spread themselves concentrically from the source of motion.

For convenience of explanation, a ray of light in its ordinary condition may be represented in ideal section by a circle (Fig. 33, 1), and undulations supposed to take place in two planes at right angles to each other (C, D and N, S). By means presently to be described, these two sets of waves can be separated, as at 2, C, D and 3, N, S. The ray of light, instead of having the same properties on every side, will be found to have acquired some qualities peculiar to the state in which it now is, and which may be named the properties of sides. For instance, 2 will exhibit certain phenomena in the direction C, D which do not exist when it is examined in other directions. The same is the case with the other half of the ray (3), which exhibits similar phenomena in the direction N, S. As these properties somewhat resembled those of the poles of a magnet, the term *polarised light* was used to distinguish light so modified, and, although perhaps not the best name that could have been given, has still been retained.

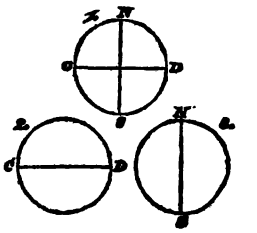
As the phenomena of interference will be frequently mentioned, it will be desirable to state what they are. The sensation affecting the optic nerve which is known as light is caused by the undulations before spoken of—light being represented by motion, darkness by rest.

Should two waves start together from the same place, they would increase each other's intensity; the result would be a wave of double height—a matter easy of comprehension, if water be considered as the medium; with the waves of air producing sound, the result would be a louder sound; and, with light, an illumination of double intensity. Should, however, one wave start before the other by the length of half a wave, the effect would be that the crest of one wave would occupy the position of the hollow of the other, and so fill it up, producing a dead level. The result would be, with water, calm; with air, silence; with light, darkness.

This is known to be the case, in some instances, where the streams from two channels meet in the manner just mentioned: perfectly smooth water is produced, although, before meeting, the surface of both may be violently agitated.

Should the waves of light start at an interval of less than half a wave, they will, by interference, be

Fig. 33*.



broken up into smaller waves, the magnitude of which depends upon the distance one wave has had the start of the other. These small waves produce coloured light, the red wave being the longest, and the violet the shortest. Mr. Woodward gives the following as the lengths of the waves of the various coloured rays of the spectrum:—Red, 266; orange, 240; yellow, 227; green, 211; blue, 196; indigo, 185; violet, 167. The figures represent the numerators of fractions, having as a common denominator the ten-millionth of an inch.

These coloured waves may be produced in various ways; for instance, by very thin plates of transparent substances, such as mica, films of oil or varnish floating on water, and films of air enclosed between transparent solid surfaces, which, by causing a slight difference in the distance of the starting points of the two series of waves of white light reflected from the upper and lower surfaces of the film, sets up interference, and breaks up the waves of white light into smaller coloured ones. The films of varnish were very ingeniously taken up from the surface of water on enamelled cards, by Mr. De la Rue, giving them a beautiful iridescent appearance. Other examples may be found in the feathers of certain birds, as humming birds, peacocks, &c., which possess a metallic lustre produced in the same manner. A minutely grooved surface will also

* The substance of a course of lectures delivered to the members of the Quekett Microscopical Club, January—April, 1869.

* Brooke's "Natural Philosophy," published by Churchill.

produce similar effects; for example, mother-of-pearl, which consists of a series of thin plates of shell, separated by folds of membrane, producing a grooved structure; also in the finely-ruled gold ornaments known as "Barton's buttons," and the minute specimens of ruling on glass by Nobert, all of which produce brilliant metallic tints by the interference of the two waves reflected, one from the surface, and the other from the bottom of the groove.

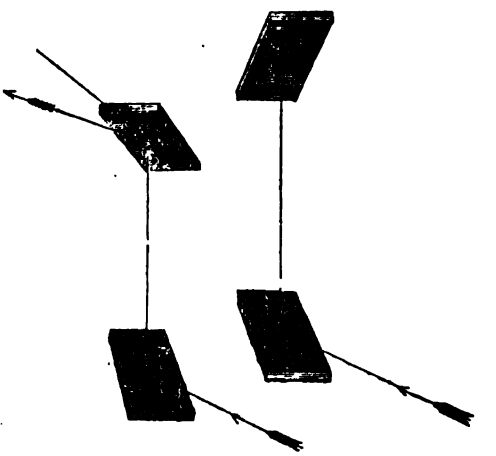
If a convex lens of extremely shallow curvature be placed upon a plane glass surface, and an arrangement be provided for exercising delicate and uniform compression, a series of circular concentric coloured bands will be seen; these are known as "Newton's rings," and are caused, as before, by the interference of the reflections from the film of air contained between the lenses; and as, from the curvature of the lens, the film is of a thickness increasing from the centre to the circumference, a variety of tints are formed at every change of thickness, the rings consisting alternately of groups of colour and dark bands, the latter being the places where total interference takes place, and darkness or rest is the consequence. These dark spaces are much better seen when the apparatus is viewed by a monochromatic light, such as that produced by the flame of a large spirit-lamp the wick of which has been sprinkled with common table-salt. Not only will the dark bands be sharper and more intense, but they will also be considerably increased in number. These rings may often be seen when plane glass surfaces are unequally compressed; for example, a piece of thin cover-glass pressed on a slide with a stick, and sometimes between the thick plate and glass negative in a photographic printing frame.

The undulatory motion of light would seem to be expressed with considerable clearness in the first chapter of Genesis when read in the original Hebrew, which, in common with the other languages of the same family, is remarkable for the numerous inflexions of its verb, which gives it a delicacy and precision of expression unattainable in Western languages. The first verse concludes:—"And the Spirit of God *moved* upon the face of the waters." This sentence immediately precedes the command that light, which may here be taken in its largest sense, including electricity and the other forces, should exist. The Hebrew word translated "moved" is more accurately expressed by *fluttered*; the same inflexion of the verb is used in this sense in the only other place in which it occurs, viz., Deuteronomy xxxii., 11., where it refers to the fluttering of an eagle over its nest. It is certainly a very remarkable expression, and the author believes that its bearing on the subject of light has hitherto escaped notice. The view that the word "light" includes the other forces, and which we have every reason to believe are but different manifestations of them, is supported by the fact, that sources of light proper or luminaries are not mentioned until the fourteenth verse, while the atmosphere or "firmament" of the English version, land, and water, and vegetable life, were all in existence, and under the influence of these mysterious powers of nature, respecting which the undiscovered and unknown probably far exceeds the little that science has at present made us acquainted with.

Light may be polarised in several ways. If a ray of light falls upon glass at an angle of 56° 45', one-half (Fig. 34) will be transmitted, the other half reflected; and, if, instead of a single plate, about ten sheets of thin window-glass be employed, the result will be much more perfect. The reflection, whether one or more plates be used, will be much improved by either coating the back with black-varnish, or placing in contact with it a piece of black cloth or velvet, which will absorb the transmitted portion of the ray. If the light so reflected be examined by another glass mirror, placed at the same angle, and so mounted that it can be moved horizontally in a circular direction, it will be found that, in some positions, the light will be reflected, while, at others, it will pass through, or be absorbed if the back is blackened. These intervals of reflection and transmission occur alternately at every quarter revolution of the upper mirror or analyser, corresponding with the points in Fig. 33, I, marked C, D and N, S.

If a ray of light be passed through a crystal of Iceland spar, one portion will be refracted according

Fig. 34.



to the usual law;* the other half will be refracted in a different direction. And, if these two rays of light be examined with an analyser, they will be found, as in the case of the reflected light, to have acquired the property of sides, or to be polarised. The ray refracted in the common way is known as the ordinary ray. The other, which is polarised in a plane at right angles to it, is termed the extraordinary ray. If a crystal of Iceland spar be placed on a sheet of paper having a black spot on it, the double refraction will cause the formation of two images of the spot or other device drawn on the paper.

(To be continued.)

ON THE

ESTIMATION OF PEROXIDE OF MANGANESE IN MANGANESE ORES.

By E. SHERER and G. RUMPF.

The method of Fresenius and Will for the estimation of manganese, to which for so long preference has been given, has recently been objected to in England by the consumers of the ore. Attention has been called to the fact that this method shows, indeed, correctly the proportion of binoxide of manganese in the sample, but, on the other hand, does not represent its value as an agent for the production of chlorine.

* Chemical News, vol. xx., p. 145.

The reason for this is that metallic iron or its proto-compounds, which are often present in the ore, absorb oxygen to form a sesqui salt when the sample is treated with hydrochloric acid, but remain unchanged when it is treated with concentrated sulphuric acid and oxalate of soda.

In consequence of this, the method of Fresenius and Will is still used in some laboratories, while, in others, it has been superseded by the iron method; from which circumstance an uncertainty in the valuation of the article arises, disagreeable alike to purchasers and sellers.

This has led us to subject the various methods to a careful examination and comparison one with another. Our object was to ascertain, by a series of experiments, how far the estimations by the same method agreed one with another, and then to discover the causes of the differences that have been observed between the results obtained by the different methods.

A sample of American manganese was used for our experiments. A large quantity was pounded, well mixed, and carefully dried at 100° C. The moisture amounted to 0·749 per cent. Quantities of the dry manganese were then at once weighed off for the various tests.

I. *According to the Method of Fresenius and Will.*

Years of experience having proved to us the constancy of results obtained by this method, we considered that three trials would be sufficient. These served to show the actual amount of binoxide in the sample.

1. 2·1098 grms. manganese caused the evolution of 1·355 grms. carbonic acid = 63·49 per cent.

2. 1·5103 grms. manganese caused the evolution of 0·970 grms. carbonic acid = 63·49 per cent.

3. 1·3645 grms. manganese caused the evolution of 0·8770 grms. carbonic acid = 63·53 per cent.

II. *According to the Iron Method.*

The estimations by this process were conducted in the following manner:—

A weighed quantity of pianoforte-wire was dissolved in hydrochloric acid, in a glass flask. Carbonic acid was conducted into the flask during the operation, to prevent the oxidation of the protochloride of iron produced by oxygen from the atmosphere. When complete solution had taken place, a small tube, containing an accurately-weighed quantity of the manganese, was dropped into the flask, the mixture boiled until complete decomposition had taken place, and then cooled in the stream of carbonic acid. The excess of the protochloride was then estimated in the usual way, by means of a standard solution of bichromate of potash. The weight of the iron wire, multiplied by 0·997, was taken as the amount of pure iron used.

1. 0·8748 grms. manganese 1·0796 „ pure iron	Chromate of potash used 22·7 c.c. = 62·00 per cent.
2. 0·7504 „ manganese 1·03668 „ pure iron	Chromate of potash used, 25·85 c.c. = 62·35 per cent.
3. 0·8746 „ manganese 1·1686 „ pure iron	Chromate of potash used, 27·65 c.c. = 62·54 per cent.
4. 0·7604 „ manganese 0·9692 „ pure iron	Chromate of potash used, 21·45 c.c. = 62·20 per cent.
5. 0·9312 „ manganese 1·3846 „ pure iron	Chromate of potash used, 38·2 c.c. = 61·97 per cent.
6. 0·5467 „ manganese 1·2183 „ pure iron	Chromate of potash used, 46·8 c.c. = 61·39 per cent.
7. 1·135 „ manganese 1·0787 „ pure iron	Chromate of potash used, 10·2 c.c. = 62·07 per cent.
8. 1·0446 „ manganese 1·0792 „ pure iron	Chromate of potash used, 14·6 c.c. = 62·01 per cent.

We therefore conclude, from these figures, that this method, proceeded with in the way we have described, does not yield accurate results.

III. *The Estimation of Manganese by the Formation of Chloride of Lime.*

The advantage that this method would seem to have over all others is that the manganese is treated in precisely the same manner in the laboratory as it is on the large scale in the manufacture of bleaching-powder.

Weighed quantities of the sample were treated with strong hydrochloric acid in a small flask until complete decomposition had taken place. The chlorine produced was conducted first into another flask, and then into a U-tube, both of which were filled with a weak milk of lime. The resulting chloride of lime was then tested by Gay Lussac's method, with arsenious acid.

	AsO_3. c.c.	per cent.
(1). 1·0561 grms. manganese	53·90	= 62·60
(2). 1·0845 „ „	56·05	= 63·39
(3). 1·2045 „ „	61·70	= 62·83
(4). 0·4222 „ „	20·70	= 60·14
(5). 0·8102 „ „	39·75	= 60·18
(6). 0·4929 „ „	23·15	= 59·06
(7). 0·4875 „ „	23·15	= 58·15

These figures sufficiently prove that no accurate results are to be obtained by this method.

We next experimented on Bunsen's method.

Weighed quantities of manganese were dissolved in hydrochloric acid in the same manner as in the preceding. The escaping chlorine was received in a strong solution of iodide of potassium, and the liberated iodine subsequently estimated by means of a standard solution of hyposulphite of soda and a solution of starch. To prevent the solution of iodide of potassium from being sucked back into the generating-flask, a few small pieces of magnesite were introduced with the manganese, so that a continual slight escape of carbonic acid took place through the solution.

The solution of hyposulphite of soda was proved by means of a carefully-prepared pure iodine. 3·0436 grms. were dissolved in iodide of potassium, and diluted to 250 c.c. 10 c.c. of this solution required 17·90 c.c. of the hyposulphite of soda solution. 1000 c.c. of hyposulphite of soda solution would, therefore, correspond to 2·3294 grms. of binoxide of manganese. A second trial, in which 2·4767 grms. of the pure iodine were used, 1000 c.c. of the hyposulphite were found to correspond to 2·3319 grs. of binoxide of manganese, which two results closely agree. In testing the manganese—

	NaO,S_2O_2. c.c.	per cent.
(1). 0·6472 grs. manganese	35·8	= 62·76
(2). 0·6427 „ „	34·6	= 62·73
(3). 0·6035 „ „	32·5	= 62·73

These results agreed so closely that we considered further estimations by this method to be quite unnecessary.

If we now compare the various results, we see that the sample, according to the method of—

	Average. per cent.	Greatest difference. per cent.
Fresenius and Will showed	63·50	.. 0·04
Iron method showed	62·06	.. 1·15
Chloride of lime estimation showed	60·90	.. 5·24
Bunsen's method showed	62·74	.. 0·03

From this, we see that only the methods of Fresenius and Will, and that of Bunsen, give constant results; and, of these two, the latter-named undoubtedly represented the value of the ore as an agent for the production of chlorine, since only the chlorine evolved from the sample in the form of gas is estimated. We therefore may conclude that the method of Fresenius and Will gives results too high, while the iron and chloride of lime methods give results much too low. Our next step was to discover the reason for these differences. The cause of the high result obtained by the method of Fresenius and Will has

already been mentioned at the commencent of this paper. We did not consider it necessary to examine whether or no the sample on which we were operating actually contained iron or its proto-compounds. The object we had in view was a purely practical one; and the possibility of the presence of such iron compounds in the ore cannot be disputed. The following experiment proves that a very considerable addition of metallic iron will not in the slighest degree affect the accuracy of the results obtained by this method. 1·4706 grms. of metallic iron were added to 2·4745 grms. of the manganese, concentrated sulphuric acid added, and the test proceeded with as usual. The result obtained—viz., 63·13 per cent—differed only by 0·37 per cent from the average of the three previous trials made by this method, notwithstanding that the amount of iron added was sufficient to render three-quarters of the manganese unavailable as an oxidising agent when dissolved in hydrochloric acid. Since varieties of manganese ore do contain the iron compounds of which we have spoken, we did not further investigate the question whether or no this was the only cause of the two high results which this method yields under certain circumstances. The reason of the uncertainty of the results obtained by the iron method, as, also, of their being generally too low, we discovered to be, that a slight loss of chlorine generally takes place during the operation. When the manganese is added to the protochloride solution, a greater or less quantity frequently floats on the surface of the liquid for a short time. A small quantity of chlorine is evolved from this, which has no opportunity of acting on the iron solution, and is carried off with the stream of carbonic acid. We convinced ourselves that this was the case by conducting the escaping gas into a second flask, which contained a small quantity of weak protochloride of iron solution. As soon as the manganese rose to the surface of the liquid in the decomposing-flask, a yellow colour appeared in the liquid in the second flask, proving that a portion of the chlorine from the manganese escaped into the second flask, and there formed a sesquichloride of iron. The contents of the two flasks were then separately tested with the chromate of potash solution. From the first flask alone, the sample would seem to contain 2 per cent less than it actually does contain.

0·8129 grms. manganese.	
1·06519 grms. pure iron in first flask.	
25·8 c.c. chromate of potash used for first flask	60·48 per cent
0·989 grms. pure iron in second flask	
57·02 c.c. chromate of potash used for second flask	1·99 per cent
	62·47 per cent

This figure agrees tolerably well with the result obtained by Bunsen's method. This method can, therefore, be made to yield accurate results, but only by a difficult and troublesome arrangement, which makes it more complicated and longer than that of Bunsen. Instead of metallic iron, a proto-salt—such as the double sulphate of iron and ammonia—is sometimes used in the iron process, and the decomposition of the manganese effected by means of weak sulphuric acid. No loss of gas probably takes place in this method. Experience has shown us that it is very difficult to obtain such salts perfectly free both from sesqui-compounds of iron and moisture. We did not, therefore, experiment on this method.

The reason of the great irregularity in the results obtained by the chloride of lime method is easily perceived. At 40° C., chloride of lime commences to be decomposed into chlorate of lime; so that a greater or less speed in the evolution of the gas will produce a greater or less warmth in the milk of lime, and, consequently, more or less decompose it. We endeavoured, by external cooling, to prevent this warming and decomposition, but with no satisfactory results, as the following figures will show. The milk of lime was cooled by the external application of a mixture of sulphate of soda and hydrochloric acid.

		AsO_5. c.c.	per cent.
(1).	0·3633 grms. manganese	18·90	= 63·80
(2).	0·7778 ,, ,,	38·45	= 60·64
(3).	0·8185 ,, ,,	40·50	= 60·70
(4).	0·9204 ,, ,,	46·25	= 61·64
(5).	0·6975 ,, ,,	35·65	= 62·69
(6).	0·5581 ,, ,,	26·85	= 59·01

This method can, therefore, only be used for approximate results.

In estimating the manganese by the method of Bunsen, the iodine liberated by the chlorine should be tested as soon as possible after the decomposition. The iodine solution from the tests numbered 1 and 2 were again tested after standing twenty-four hours. The results were both over 65 per cent. This was caused by the conversion of iodine into hydriodic acid. In conclusion, therefore, we may decide that the results obtained by Bunsen's method exceed all others in accuracy. Its simplicity, also, is greater than that of the iron method, as it requires only one weighing, and does not need a stream of carbonic acid. At the mines where tests continually have to be made, the method of Fresenius and Will would certainly appear to be the best and simplest, so much the more that here no accidental admixture of iron can have taken place.

In conclusion, we would suggest that it is more reasonable to represent the value of manganese rather by chlorometrical degrees than by the percentage of binoxide. Neither the method of Bunsen nor the iron method represent the percentage of binoxide, but the relative value of the ore as an agent for the production of chlorine; and, therefore, a similar form of expression for the value of chloride of lime and manganese, seems to us desirable.

Wiesbaden, Oct. 11th, 1869.

PS. The foregoing paper is the result of experiments made at the laboratory of Dr. R. Fresenius, in Wiesbaden.

ON SOME

TECHNICAL APPLICATIONS OF THE SPECTRUM MICROSCOPE.*

By H. C. SORBY, F.R.S., &c.

(Continued from p. 296.)

Adulterations of Wine.

The only cases in which the spectrum method can be easily applied to detect adulterations in wines are when some colouring matter has been introduced to give a false appearance of age, or to bring the colour up to some desired standard. According to Payen's interesting work,† logwood and Brazil wood were at all events employed a few years ago for this purpose; and rhatany root and the berries of the so-called *Virginian Poke* (*Phytolacca decandra*) are sometimes used. I mention these because I purpose to briefly describe how they may be detected, as an illustration of the methods which may be employed in such investigations. I must, however, confess that I have not detected these substances in any wines of commerce that I have yet examined; but then I have had very little opportunity for studying those likely to contain them.

In order to detect logwood or Brazil wood, a small quantity of the wine should be agitated in a test-tube with an equal volume of ether, which rises to the surface in an almost colourless state if the wine be pure, but is tinged with a more or less strong yellow when either of the above-named substances is present. The etherial solution should be transferred to a small evaporating dish by means

* Communicated by the author, having been published in the *Quarterly Journal of Microscopical Science*, vol. ix., new series, p. 358.

† "Précis des Substances Alimentaires," note at p. 455.

of a pipette, and a fresh quantity of ether agitated with the wine, and added to the other. The most useful kind of pipette for this and similar purposes is one with a small vulcanised india-rubber top, so arranged that, after having been compressed, it may, by its own elastic force, draw up the liquid. After evaporating the solution to dryness, a small quantity of the colour should be dissolved in water in an experiment cell, and treated with bicarbonate of ammonia. In both cases this developes a single very distinct absorption band in the green, that characteristic of logwood being situated at 4¾ of my scale, whilst that of Brazil wood is farther from the red end, at 5¼; and the solution is strongly fluorescent, of a peculiar orange colour. These spectra are so characteristic, and can be so easily compared with those of the substances themselves, that an extremely minute quantity of either could be detected with certainty.

The colour of rhatany root does not give any well-marked band in an aqueous solution, either acid or alkaline; but when dissolved in alcohol and slightly acid, it shows a moderately distinct band between the yellow and green, at 3¾ of my scale, and a fainter at 7¼. In order to detect this substance the wine should, therefore, be evaporated to small bulk, and re-dissolved in strong alcohol, and after this has stood in a test-tube until the insoluble matter has been deposited and the solution has become quite clear, the absorption band at 3¾ may be more or less distinctly recognised, according to the amount of the rhatany root present; but the natural colour of the wine makes it impossible to detect a very small quantity.

The dark crimson berries of the Virginian poke are remarkable for containing a colour belonging to my group C; whereas those of nearly all fruits of that tint belong to group B. It shows two absorption bands, which are more distinct in an alcoholic than in an aqueous solution, and are 4¾, 7¾. To detect this substance we ought, therefore, to adopt the same process as in the case of rhatany root, and endeavour to see those bands, which might sometimes be made more distinct by adding a little water and sulphite of soda.

These substances may be changed by keeping long in solution, and therefore might not be detected in old wines.

On the Application of the Spectrum Microscope to the Chemistry of Beer.

In studying the colouring matters in beer, it is, in the first place, desirable to understand those met with in the various substances used in brewing; but it is unnecessary to take into consideration colours insoluble in water.

When malt is digested in hot water, an orange-yellow colouring matter is extracted; but the solution contains so much sugar and gum as to interfere with the necessary experiments. It should, therefore, be evaporated to the consistency of syrup, alcohol added by degrees, and the precipitated gum and sugar well stirred up, so that as much colouring matter as possible may be dissolved. After standing till quite clear, this solution, on evaporation, yields a pale orange-yellow syrup, which, when dissolved in water or alcohol, gives a spectrum without any decided characters. Ammonia makes it a deeper and brighter yellow; and the same change occurs when it is dissolved in sulphuric acid. In all these experiments, a mixture of equal volumes of the concentrated acid and water should be used; for, if much stronger, it chars vegetable substances, and, if weaker, it does not act well with the reagents added to it. When dissolved in this, the colour of malt is made much darker by the addition of nitric acid or chlorate of potash; but an excess of the latter makes it rapidly fade to a pale yellow, whilst hypochlorite of soda, in small quantity, makes it somewhat more orange, and more makes it a very pale yellow. The characteristic test is hypochlorite of soda, added to an aqueous or alcoholic solution in which a little citric acid has been dissolved. The addition of a suitable quantity of the hypochlorite turns the aqueous solution to a pink flesh-colour, becoming deeper; but it is not clear, and, on standing, a copious pink flocculent deposit subsides. When seen to the greatest advantage, the spectrum is 4 . . . 8 . . 10 . . 11—, without any decided narrow absorption bands. If, however, the colour was dissolved in alcohol, the solution remains clear; there is a well-marked band at the yellow end of the green, which at first is 4¾, and, as the colour becomes deeper, is more distinct, and rises to 5. The flesh-coloured deposit from the solution in water is easily dissolved by alcohol, and gives the same spectrum; and these facts are so unique that this colouring matter could be easily recognised in complicated mixtures. It certainly does not occur in barley, and must, therefore, be formed in the process of malting. Water extracts from barley a brown colour, insoluble in alcohol, which exactly corresponds with that of liquorice; and also a yellow colour, soluble in spirit, which does not exactly correspond with that obtained from hops, but yet differs from it in such a manner that, taking all the facts into consideration, it seems probable that it is the same colour in a less pure condition.

When hops are boiled in water, the solution evaporated, and the gum, &c., removed by alcohol, as already described, an orange-yellow colour is obtained which, in general appearance and in its behaviour with most reagents, is extremely similar to that from malt. It may, however, be easily distinguished by the action of hypochlorite of soda; for, when this is added to an aqueous solution previously treated with a little citric acid, it merely changes it to a very pale yellow, without any shade of pink. This colour, or, at least, colours, which I have not been able to distinguish from it, is met with in several kinds of faded leaves, stems, and roots, and seems to be very generally distributed.

When the partially-charred malt used in brewing porter is digested in water, a dark solution is obtained; and, on evaporation to small bulk and treatment with alcohol, nearly the whole of this dark colour is precipitated along with the gum. To obtain it more pure, it may be re-dissolved once or twice in a little water, and re-precipitated by alcohol. When dissolved in water, it gives an orange-brown solution, with a spectrum . . . 4 . . 5 . . 6—, made somewhat darker by ammonia; and, when dissolved in sulphuric acid, the colour and spectrum are nearly the same. Oxidising reagents do not make it any darker in either solvent, but merely cause it to fade to a pale yellow.

Besides this dark colour, highly-dried malt contains an orange-yellow, soluble in both strong alcohol and water. This differs from that obtained from pale malt, in not being turned at all pink by the action of hypochlorite of soda, and is distinguished from the colouring matter of hops or of beer (with which it agrees in general colour) by not being made at all darker by the addition of oxidising reagents to the solution in sulphuric acid, as if it were already in an oxidised condition.

Liquorice is chiefly coloured by a brown substance, which closely resembles that present in dark malt. When alcohol is added to the strong aqueous solution, it is precipitated in the same manner; and when dissolved in water the general colour is very similar, though rather more orange. They may, however, be easily distinguished by the action of oxidising reagents. If to solutions in sulphuric acid of equal depth of colour equal quantities of chlorate of potash be gradually added, the malt first becomes a much paler orange, and then pale yellow; whereas the liquorice turns to an orange, which does not become pale until very much more chlorate has been added than suffices to make the malt very pale. Though they can thus be easily distinguished, yet when mixed together, as in porter, it is not easy to obtain decided results. The change of colour is very similar in kind, and differs only in degree; so that the addition of too much chlorate may make the liquorice as pale an orange as the malt; and

when not much liquorice occurs mixed with malt, it becomes very difficult to recognise it. Still, however, with care its presence may be detected in ordinary porter.

That colouring matter of porter which is soluble in strong alcohol behaves with reagents like a mixture of those from beer and dark malt. Hypochlorite of soda turns the solution in sulphuric acid to a red, but of a less deep tint than in the case of beer.

The sweet wort obtained in brewing contains the colour of malt, already described, and, after boiling with hops, the hop colour; but after fermentation a change is found to have occurred, which proceeds still further when the beer is kept in the barrel. This change is best shown by the addition of hypochlorite of soda to the solution of the colouring matter in sulphuric acid. The gum, &c., should be removed by means of alcohol, in the manner already named when describing malt. Taking two experiment cells, and dissolving in one the colour of the unfermented wort, and in the other an equal quantity of the colour of beer that has been kept some months in barrel, the general tint is seen to be very similar. Since the solutions are otherwise apt to be turbid, it is best to fill the tubes three-fourths with the sulphuric acid diluted with an equal bulk of water, and then to fill up with alcohol, after which the coloured syrup can be added on a platinum wire, and made to dissolve by stirring. On adding little by little hypochlorite of soda to such a solution of the unfermented wort, it first turns it a little more orange, and then pale yellow; whereas, in the case of the beer kept in barrel, it is first gradually changed to a deep pink-red, which, when strong, is 3 - - 4—, and, when seen to the greatest advantage is 5 - - 7½ . . . 9½ - - 10—, having, therefore, a broad absorption band at 6½. On adding more hypochlorite it becomes more orange, and finally an orange-yellow. The fermented wort behaves in an intermediate manner; and hence it should appear that the change begins during fermentation, and is continued when the beer is kept in barrel. Still, however, it does not seem to depend simply on fermentation, since no such change occurs when fermented on a small scale; and, therefore, it may perhaps be due to deoxidisation, which would be more likely to take place in a large quantity less exposed to air.

If in any case it were desirable to ascertain whether or no any mixed liquid contained beer, the various reactions with the reagents already mentioned might enable us to form a very decided opinion when other tests failed; but so much would depend on the circumstances of the case that no general rule could be given.

(To be continued.)

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, December 16th, 1869.

Dr. A. W. Williamson, F.R.S., &c., President, in the Chair.

The minutes of the previous meeting having been read and confirmed, the following certificates were read:—

For the first time:—Pedlar, Royal College of Chemistry.

For the second time—James Bell, Howell Hill, Ewell; G. R. Hislop, Gas Works, Paisley; William Ladd, Beak Street, Regent Street; Alfred Bird, Worcester Street, Birmingham; H. Seward, 15 Barnsbury Park, N.; Edwin Lepper, 11, Maiden Lane, Queen Street, Cheapside, E.C.

For the third time—Samuel Jefferson, Secretary to the Yorkshire Board of Education, Woodville Terrace, Woodhouse Lane, Leeds; Clements Higgins, Demonstrator of Chemistry, King's College, London; James John Bourey, Analytical Chemist, 10, Stepney Causeway, E.

The last-named gentlemen were ballotted for and duly elected.

Mr. McLeod gave a verbal account of some experiments he had made on the presence of gases in sea water. At the last meeting he had stated from memory that Thames water contained 6 volumes of gas in 100 of water: on referring to his note-book he found that 100 vols. of this water contained—Nitrogen, 1·398; oxygen, 0·619; carbonic anhydride, 4·180; giving a total of 6·197 vols. in 100 vols. of water. He had experimented upon some sea water collected at Worthing, some distance from the outfall of any river, and which had been exposed to the air for twenty-one months, and found that the amount of gas in 100 vols. was—Nitrogen, 1·104; oxygen, 0·572; carbonic anhydride, 2·620; the total being 4·296. This was very much in excess of the quantity found by Mr. Hunter, as recorded in his paper read at the last meeting, but the quantity of carbonic anhydride was much smaller than might have been expected. The hardness of sea water was greater than that of Thames water, and therefore one would expect a larger quantity of anhydride to have been produced by the distillation. He intended, if possible, to collect some water from the surface of the sea, and to ascertain what quantity of gas it contained.

The President, in thanking Mr. McLeod for his communication, said Dr. Hugo Müller had, he thought, made experiments on the condition of carbonic gas when dissolved in water which led to remarkable results.

Dr. Hugo Müller, in experimenting on the manufacture of soda-water in an apparatus which was formerly much used, found that if the carbonic acid remained in contact with the water for twenty or twenty-four hours, it disengaged itself gradually, adhered to the sides of the glass, and appeared altogether different than when it was left only a short time in contact with the water. He had also noticed that, with the addition of a little common salt, the carbonic acid dissolved much quicker, the chloride of sodium being actually decomposed by the carbonic acid, hydrochloric acid and bicarbonate of soda being formed. He had proved the presence of hydrochloric acid, by ultramarine, which was neither acted upon by carbonic acid nor chloride of sodium. Another instance, in which the chloride was decomposed by carbonic acid, was when carbonic acid was passed through a neutral solution of chloride of lead. In a short time, a clear solution was obtained, and, after a certain time, a precipitate consisting of chloro-carbonate was formed.

Dr. Divers observed that, if rectified spirit were mixed with distilled water which contained air through exposure, a kind of effervescence occurred, which he supposed was due to the formation of minute bubbles of air being liberated and rising to the surface. This seemed to show that a mixture of spirit and water had less solubility for air than pure water itself.

The President wondered if the temperature had anything to do with the peculiar state in which Dr. Hugo Müller found the carbonic acid. He had been looking over Dr. Andrews's experiments on the states of carbonic acid at different temperatures, and it would seem that a few degrees of temperature made a great deal of difference in the proportion of the acid, which was not overcome by enormously multiplying the pressure. The observations on the greater solubility of carbonic acid in water containing sodic chloride he thought of great theoretical value, confirmed as they were by the ultramarine test. He (the President) had held, for years, that salts generally dissolved in water by decomposition, and he was interested to find his view confirmed by the introduction of the ultramarine test for the presence of free hydrochloric acid.

After some further remarks from Dr. Hugo Müller, on the chloro-carbonate of lead reaction,

The President alluded to a reaction he had published twenty-four or twenty-five years ago—viz.,

the action of chlorine in water in the presence of salts like sodic sulphate.

The meeting was then adjourned to January 20th, 1870.

GLASGOW PHILOSOPHICAL SOCIETY.

(Chemical Section).

The ordinary meeting of this section was held on the evening of Tuesday last, Dr. Wallace, F.R.S.E., one of the Vice-Presidents, in the chair. Several new Associates were balloted for and admitted. Thereafter,

Mr. W. R. Hutton, manufacturing chemist, read a paper "*On the Chemistry of Coal-Smoke.*" The author glanced at the subject both in its sanitary and its economical aspects; and then, in order that the scientific principles involved in the prevention of smoke, and in the complete utilisation of the heating power of raw coal, might be properly understood, he gave an analysis of best Wishan coal, one of the finest kinds of fuel in Scotland. It was as follows:—

Water	2·8
Sulphur	0·4
Volatile matter	36·9
Fixed carbon	56·3
Ash	3·6
	100·0

Volatile Matter.

Carbon	14·0
Hydrogen	6·0
Oxygen	15·9
Nitrogen	1·0
	36·9

In the ordinary combustion of coal, black smoke, and therefore soot, is only producible from the volatile matter of the coal, the fixed carbon, ash, &c., being incapable of generating smoke. The value of a fuel as a generator of heat is estimated according to the amount of carbon and hydrogen present in it. As ordinarily used, coal, during its combustion, gives rise to many curious compounds, including carbonic oxide, carbonic acid, watery vapour, ammonia, sulphurous and sulphuric acids, and various hydrocarbons, some of the paraffin series, and others of the naphthalin series; and, as they are volatile when liberated, they rise into the atmosphere and form the mixture known as coal-smoke. This material differs in its properties and composition, according to the composition and mode of burning the coal; but, in all cases, sooty carbon and moisture are abundant, the former especially so in black smoke. But black smoke is soot, and is the result of the imperfect combustion of the coal, and even of its wasteful use. Mr. Hutton then went on to examine soot in its chemical aspects, and explained, in detail, how the difference of temperature in a furnace or domestic fire regulates the composition of the volatile matters of soot. The composition of London and Glasgow soot was shown in a table, of which the following is a copy.

Analysis of Soot.

	London.	Glasgow.
Carbon	53·18	35·7
Tar and oil	18·00	15·0
Ammonia	1·75	2·8
Potash	0·20	0·3
Soda	0·34	0·3
Lime	1·00	0·8
Magnesia	0·30	trace
Phosphate of lime and alumina	2·08	3·2
Iron	0·40	0·7
Sulphuric acid	4·60	7·9
Chlorine	trace	0·4
Sulphocyanogen	0·25	none
Carbonic acid	0·70	trace
Sand	14·40	25·7
Water	2·80	7·2
	100·00	100·0

The author said he could guarantee the genuineness of the sample of London soot; but he was afraid that the Glasgow soot which he had examined was adulterated, judging by the large percentage of sand and water contained in it. The large proportion of sulphuric acid might be accounted for by the sulphurous quality of the Scotch coal, and by the great number of chemical works in Glasgow. Genuine Glasgow soot ought to contain a larger amount of ammonia: both samples were distinctly acid. While referring to the various uses of soot, Mr. Hutton mentioned that a considerable quantity was recently shipped to the West Indies, to be used there for the growth of the sugar-cane. The price is from 30s. to 40s. per ton. Considering that soot rarely contains less than about one-sixth of its weight of hydrocarbon compounds, the author of the paper proceeded to look at the production of soot from a commercial point of view, and asked if the value of soot is proportionate to the evils resulting from the production of the material. Not more than 500 tons are gathered in Glasgow per annum, and the value never exceeds £1000. Taking the waste of fuel, the loss of the nitrogen of the coal, the destruction of property, and the personal discomfort resulting from smoke and soot, he found that there was no profit. but rather a great loss instead. As a practical solution of the "smoke nuisance," Mr. Hutton briefly sketched a plan by which practically smokeless fires might be obtained, while all the volatile compounds could be separately collected, and be got in a form fit for utilisation. He would distil the coal before burning, stopping short the process of distillation at such a stage as would permit *soft coke* to be formed—that is, fixed carbon with a sufficient amount of volatile matter in it to render it slightly inflammable. The other useful products would be chiefly crude oil, coal-gas, and ammonia. Assuming, as a basis of calculation, 2000 tons of coal to be used daily, that amount would yield, in round numbers—

Soft coke	1400	tons.
Crude oil	40,000	gallons.
Ammoniacal water	30,000	,,
Coal gas	6,000,000	cubic feet.

Deducting the ash, the fixed carbon would be reduced to 1329 tons. Mr. Hutton calculated that the coke and the other products would realise £742, while the coal (at 5s. per ton) and the labour, &c., would cost £600, leaving an apparent balance of £142, in addition to all the other advantages which would result from the complete combustion of the fuel. The coke would be such a material as would be available alike for domestic fire-places and the furnaces of steam-boilers, &c.

At the conclusion of the paper, various members spoke in commendation of Mr. Hutton's views. In reply to Mr. Stanford,

Mr. Hutton stated that such coke as he had suggested in his paper could be burned in the ordinary grate, without the expense or any other of the inconveniences attending the use of the grate which was devised some years ago by the late Dr. Neil Arnott.

On the motion of the Chairman, a codial vote of thanks was awarded to Mr. Hutton; and the meetings of the Section were adjourned for a month.

The Faraday Memorial.—The subscriptions to the Faraday Monument Fund, received up to Dec. 7, amount to £1400. The object of the fund is to provide a public memorial to Faraday, and the subscription from one person is not to exceed five guineas.—*Nature.*

NOTICES OF BOOKS.

The Life and Letters of Faraday. By Dr. Bence Jones, Secretary of the Royal Institution. London: Longmans, Green, and Co. 1870. 2 vols., 8vo., with illustrations.

II.

The second volume of this work is divided into four chapters, of which the first treats of Faraday's "First Period of Electrical Research," included between the years 1831 and 1840, and extending to his forty-ninth year. The great discoveries of this period of his life were those of magneto-electricity and of definite electrical decomposition, So early as 1831, we find the germ of the idea of "lines of force"—an idea which pervaded all his succeeding philosophy. "By magnetic curves," he writes, "I mean lines of magnetic forces which would be depicted by iron filings." The first series of his "Experimental Researches in Electricity" was the result of ten days' labour, and was read on November 24th, 1831, at the Royal Society. The full course of these researches, together with the dates, has been so carefully noted by Dr. Bence Jones, in the notice of Faraday which appeared in the *Proceedings of the Royal Society* for last year, that it will be needless to enter into any detail here; moreover, the main facts of these great researches are more or less known to all of us, and require but little description. We may mention that the appendix to Chapter 1 contains an example of the notes from which Faraday lectured. On one side of a sheet of paper, he was in the habit of setting down the experiments, numbered and in order, and accompanied by divisions of the lecture-hour into intervals of minutes, varying from five to fifteen; on the other side, the notes of subject-matter were written. with figures corresponding to the numbered experiments.

The second chapter includes the years intervening between 1841 and 1844, and is entitled "Rest between the Periods of his Experimental Researches—Swiss Journal—Nature of Matter." The intense mental labour connected with the electrical researches had brought on attacks of giddiness and loss of memory, and for four years Faraday undertook but one research connected with electricity. He entirely rested during one year, even giving up lecturing at the Royal Institution; and he spent three months of this time in Switzerland. The journal which he kept during this period is full of interest, and shows us the character of the man apart from his science; and it may be here remarked that, although we are apt to study this character more in reference to Faraday's great efforts of scientific thought, it is equally worthy of minute study for other reasons, for the humanity, the gentleness, the love of truth, and the consistency, which were such prominent characteristics of the man.

In 1843, the present Emperor of the French, at that time a prisoner in the Fortress of Ham, addressed several letters to Faraday on scientific subjects. We here find the Emperor appearing in an altogether novel light—viz., as the propounder of a new theory of the action of the voltaic pile, which was read to the Academy by M. Arago, but which does not appear to have been received with much warmth. The Emperor, however, shows that he possessed some knowledge of electricity, and his remarks and inferences are by no means superficial. In some of his experiments he required a galvanometer, but could not succeed in constructing one "parceque les aiguilles aimantées furent toujours déviées par l'attraction des barreaux de fer qui entourent mes fenêtres." Sometimes he seems to have thought of applications of voltaic electricity to purposes of war:—"*What is the most simple* combination," he asks Faraday, "to give to a voltaic battery, in order to produce a spark capable of setting fire to powder under water or under ground?"

The third chapter comprises the period between 1844 and 1855, and extends to Faraday's sixty-fourth year; it discusses "Later Period of Electrical Research—Discovery of the Magnetisation of Light—The Magnetic State of all Matter—Atmospheric Magnetism." The discoveries made during this second period of electrical research were published in the eleven series of "Experimental Researches in Electricity" included between the nineteenth and the thirtieth. Although the discovery of the magnetisation of light (which Sir William Thompson has designated "the greatest discovery of this century)" was among these discoveries, Dr. Bence Jones considers that, "great as these discoveries were, they will not at the present time rank with the three great discoveries of magneto-electricity, voltaic induction, and definite electro-chemical decomposition, which made the glory of the earlier period of the 'Researches in Electricity.'"

Here are some remarks drawn at random from various lectures given at the Royal Institution during the year 1845. Speaking of the fineness of gold wire, he said—"Four sovereigns' weight of pure gold could be drawn into a wire long enough to surround the globe." In a lecture on mercury, he said—"Lecture-room, with all its walls, floors, roofs, &c., from top to bottom, and full of people, if standing in a trough of mercury having the same base as the lecture-room, would only raise a column at the sides 17½ inches high." Of the voltaic battery, he said—"This instrument has done—is doing—more in developing the internal molecular powers of bodies, and the unity of the various forces in nature, than any other offspring of human thought." Speaking of evening lectures at the Royal Institution, he said—"As to popular lectures (which at the same time are to be *respectable* and *sound*), none are more difficult to find. Lectures which *really teach* will never be popular; lectures which are popular will never *really teach*. They know little of the matter who think science is more easily to be taught, or learned than A B C; and yet who ever learned his A B C without pain and trouble?" In a letter published in the *Philosophical Magazine* for 1846, in which we find some of Faraday's boldest and grandest speculations, we have one of the many examples of the singular modesty and humility with which, even at the summit of his fame, he propounds a theory. "I think it likely," he says in concluding, "that I have made many mistakes in the preceding pages, for even to myself my ideas on this point appear only as the shadow of a speculation, or as one of those impressions upon the mind which are allowable for a time as guides to thought and research. He who labours in experimental inquiries knows how numerous these are, and how often their apparent fitness and beauty vanish before the progress and development of real natural truth."

In 1855, Faraday concluded his "Experimental Researches in Electricity." They had extended over a period of twenty-six years, and undoubtedly constitute his greatest and noblest work; the ultimate issue and result of the work it is impossible to estimate, each branch of it as left by him, nay, the smallest twig, may be transplanted, until a very forest is the result. It has stimulated, and will stimulate work; it admits of an infinity of applications; above all, it is a grand example of accurate work, combined with accurate thought, with method, with genius, with a refined manipulation, and a subtle mind. Let us glance at the main results of his electrical researches, in the order in which they occur. "The Induction of Electric Currents—The Evolution of Electricity from Magnetism—Terrestrial Magneto-Electric Induction—Identity of Electricity from Different Sources—Conducting-Power generally—Electro-Chemical Decomposition—Electricity of the Voltaic Pile—Induction of a Current on Itself—Static Induction—Nature of the Electric Force—Character of the Electric Force in the Gymnotus—Source of Power in the Voltaic Pile—The Electricity evolved by the Friction of Steam—The Magnetisation of Light, and the Illumination of Magnetic Lines of Force—New Magnetic Actions—The Magnetic Condition of all Matter—The Crystalline Polarity of Bis-

muth, and its relation to the Magnetic Form of Force—The possible relation of Gravity to Electricity—The Magnetic and Dia-Magnetic Condition of Bodies, including Oxygen and Nitrogen—Atmospheric Magnetism—Lines of Magnetic Force, and the Employment of Induced Magneto-Electric Currents as their Test and Measure—The Constancy of Differential Magne-Crystallic Force in Different Media—The Action of Heat on Magne-Crystals—The Effect of Heat upon the Absolute Magnetic Force of Bodies."

This magnificent work was done under conditions of penury; yet, "during a great part of these twenty-six years, the Royal Institution was kept alive by the lectures which Faraday gave for it." Faraday received, during the greater part of this time £100 a-year from the Institution, and nearly £100 as Fullerian Professor. He kept account of his expenditure in research and apparatus literally to the uttermost farthing. Altogether, Faraday laboured for science for fifty-two years, one-half of which time was devoted to the "Experimental Researches in Electricity."

In June, 1862, Faraday gave his last Friday evening discourse at the Royal Institution. The following are the notes which he made for this his retirement from active duties:—

"Personal explanation,—years of happiness here, but time of retirement; Loss of Memory, and *physical* endurance of the brain.

"1. Causes—*hesitation and uncertainty* of the convictions which the speaker has to urge.

"2. *Inability to draw* upon the mind for the treasures of knowledge it has previously received.

"3. *Dimness*, and forgetfulness of one's former *self-standard*, in respect of *right*, *dignity*, and *self-respect*.

"4. Strong duty of *doing justice to others*, yet inability to do so.

"5. *Retire*."

Who among those present will ever forget the intense enthusiasm which was exhibited at the conclusion of the lecture "On Platinum," nearly the last which Faraday gave? "I have desired to retire," he said, "as I think every man ought to do before his faculties become impaired; but I must confess that the affection which I have for this place is such that I hardly know when the proper time has arrived." No victor in the Olympian games, no conqueror ascending in triumph the Capitoline Hill, no *prima donna* in the height of her fame, ever received a more complete ovation.

"For thirty-eight years," says Dr. Bence Jones, "his lectures were the life of the Royal Institution. His singular power of making himself one with his audience was felt in his Juvenile Lectures, in his Theatre Courses, and in his Friday Evening Addresses." His great success as a lecturer may be attributed to his careful attention to strict rules; some of his earlier remarks on lecturing we gave in the first of these notices, the following rules were found among his notes:—

"Never to repeat a phrase.

"Never to go back to amend.

"If at a loss for a word, not to ch—ch—ch, or eh—eh—eh—, but to stop and wait for it. It soon comes, and the bad habits are broken, and fluency soon acquired.

"Never doubt a correction given to me by another."

In addition to this strict attention to rules, Faraday took lessons in lecturing in 1823, and again in 1825 and 1826, before giving his first course of lectures in the Institution.

Dr. Bence Jones closes his admirable "Life of Faraday," by a statement of the chief of the characteristics of the great philosopher, and of the qualities which combined to render him so noble and so good. "As a philosopher, his first great characteristic was the trust which he put in facts. . . . His second was his imagination. It rose sometimes to divination, or scientific second-sight, and led him to anticipate results that he or others afterwards proved to be true." As a man, his first and greatest quality was his truthfulness; the second, his kindness; the third, his energy. "His religion was a living root of fresh humility, and, from first to last, it may be seen growing with his fame and reaching its height with his glory, and making him, to the end of his life, certainly the humblest, while he was also the most energetic, the truest, and the kindest of experimental philosophers. . . . . His standard of duty was supernatural; it was not founded upon any intuitive ideas of right and wrong; nor was it fashioned upon any outward expediences of time and place; but it was formed entirely on what he held to be the revelation of the will of God in the written Word, and throughout all his life his faith led him to act up to the very letter of it.

Much has been said and written about the Faraday Memorial, and the proposition to erect a monument to him in St. Paul's cathedral is being actively advanced. Looking at his many and great works, and at this last record of him, full of his every-day thoughts and actions, we are tempted to repeat the hackneyed, but here infinitely appropriate, phrase "*Si monumentum requiris, circumspice.*" Of Faraday himself we may truly say, "Exegit monumentum ære perennius." Yet there should be some mark of the popular esteem for such a man—and if it takes the form of a statue, it should be among the quick, not among the dead. It should be in the busy world, and in the light of day, that they who pass by may stay, and read, and remember. Whoever enters St. Paul's, must feel the gloomy chill of the vast, silent edifice; all is dull and gloomy, and the surroundings recall to us obsequies, and friends mourning, and the terrors of death. We would not have the statue of Faraday placed here; we would not wish to think of him with sorrow in our hearts and ashes on our heads; but we would have the memorial in our often view, and unencompassed by aught that brings feelings of gloom and unhappiness, in that we shall see him no more. To one who asked him, during his last years, how he was, he replied "Just waiting." Let us think of the old philosopher as he sat by his window at the close of life looking out upon the green trees and fields of Hampton, and delighting in the beauties of that Nature he had loved so fondly. He who had been so strong, so mighty to prevail, was now as a little child. The *lumen purum* of the great intellect which had penetrated the mysteries of Nature as few had ever done before, was flickering, and faint, and dim. *Nunc dimittis*,—"the sweetest canticle of all when a man hath obtained worthy ends and expectations"—is the thought which fills his mind; and as he gazes into the bright world without, the landscape fades almost imperceptibly from his sight, the voice of nature is hushed, and there comes a momentary darkness, the precursor of a perpetual light.

Stereograms of Mars, with a Chart of Mars on Mercator's Projection, and Descriptive Remarks on the Stereograms. By R. A. Proctor, B.A., F.R.A.S. London: John Browning, 111, Minories.

We learn, from Mr. Proctor's remarks, that these stereograms are photographs from the globe of Mars which Mr. Browning constructed in the spring of 1868, the edges of the pictures being softened by hand. Viewed in the stereoscope, they give a singularly real and solid figure of the planet, and will not only afford the astronomer an opportunity of studying Mr. Browning's globe, but will also enable him to test the accuracy of his own observations. In producing these admirable stereograms, Mr. Browning has rendered another important service to the science of astronomy.

The Quekett Microscopical Club.—We understand that Mr. Suffolk will repeat his course of lectures "On Microscopical Manipulation" in January, 1870. Gentlemen wishing for particulars can apply to the Secretary.

LABORATORY NOTES.

AN EXPERIMENT TO DEMONSTRATE INCREASE OF WEIGHT IN COMBUSTION.

There are two or three methods given in our text-books of demonstrating the increase of weight in combustion, and recently a novel one was described in the *Berichte der Deutschen Chemischen Gesellschaft zu Berlin* (Chemical News, vol. xx., p. 71). This method consisted in burning iron filings attached to a magnet, the magnet and filings being hung over the pan of a moderately delicate balance. While preparing this experiment, another form of it occurred to me, and this I have found to answer admirably; it has, however, the disadvantage of requiring a supply of oxygen from a bag or gas-holder. The experiment is made thus:—A small patty-pan, or the lid of a tin box, is put in one pan of a balance and counterpoised; then a piece of iron wire, or a knitting pin, is placed on the pan, and this also weighed or counterpoised. The wire is now burnt before the oxy-hydrogen blowpipe, the patty-pan being held underneath the burning wire to catch the globules of iron oxide as they melt off. When the wire is burnt as far as practicable, the patty-pan with the globules of iron oxide and the portion of unburnt wire, is put into the scale-pan, and it will be found there is a considerable increase in weight, due to the oxygen which has combined with the iron.

C. J. Woodward, B.Sc.

Midland Institute, Birmingham,
December 20th, 1869.

MISCELLANEOUS.

Royal Institution of Great Britain.—The following are the arrangements for the Friday Evening Meetings before Easter, 1870:—

Jan. 21st. Professor Tyndall, LL.D., F.R.S., M.R.I.—"On Haze and Dust."

Jan. 28th. Professor Odling, F.R.S.—"On Professor Graham's Scientific Work."

Feb. 4th. Professor Ruskin, M.R.I.—"A Talk respecting Verona and its Rivers."

Feb. 11th. W. B. Carpenter, M.D., F.R.S., &c.—"On Temperature and Life in the Deep Sea."

Feb. 18th. William Kingdon Clifford, Esq., B.A.—"On Theories of the Physical Forces."

Feb. 25th. Colonel Sir Henry James, F.R.S.—"On the Results of the Excavations at Jerusalem, and on the Recent Survey of Sinai."

March 4th. E. J. Reed, Esq., C.B., Chief Constructor of the Navy.—"On Iron-clad Ships."

March 11th. Professor Sylvester, M.A., LL.D., F.R.S., —"On Chance."

March 18th. Peter W. Barlow, F.R.S.—"On the New Thames Tunnel."

March 25th. Professor Rolleston, M.D., F.R.S.,—"On History of the Fourth, Fifth, and Sixth Centuries in England, as Illustrated by Researches into the Modes of Sepulture then Practised."

April 1st. Professor Roscoe, F.R.S.

April 8th. Professor Huxley, F.R.S.

Examination of Petroleum.—We have received from the committee of the Mineral Oil Association, to which Dr. Paul is consulting chemist, a statement of results obtained in the examination of 75 samples of petroleum and other kinds of mineral oil purchased in the ordinary course from retail dealers in the Metropolis, which show—(I.) That one-half of the oil represented by these samples is petroleum within the meaning of the Act (31 and 32 Vict., cap. 56); (II.) That it gives off inflammable vapour at a temperature below that specified by the Act as the minimum for ensuring safety in the stowage and sale of such oil; and (III.) That there is still a very general and habitual disregard of the provisions of the Petroleum Act. A portion of each sample of oil tested has been preserved at the office of this Association.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the Chemical News, *with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."*

Note. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, December 6, 1869.

This number contains the following original papers relating to chemistry and allied sciences:—

Influence which Water Exercises upon the Double Decomposition of Saline Matter and upon the Thermic Phenomena by which these Decompositions are Accompanied.—M. Marignac.—This paper records the results of a series of experiments made with the view to ascertain, by the measurement of the thermal phenomena, what really takes place in double decomposition when rather dilute saline solutions are operated upon. When water is added to any solution of a salt or acid, a variation of temperature always takes place, which may be an absorption of heat or a disengagement thereof, but which does not exceed 0·2° for solutions of 1-10th, and becomes less for more dilute solutions. This rule is not, however, absolute, because the thermic effect caused by the dilution of sulphuric acid becomes greater with more diluted solutions. The figures 92, 135, 185, 255, express the caloric per equivalent (49), according to the state of the dilution, being 1-10th, 1-20th, 1-40th, 1-80th. The mixing of solutions of two salts which cannot decompose each other gives rise to thermic effects which are less marked. We regret that space forbids us now to enter into more details of this subject.

Reply to Remarks made by M. V. Regnault concerning Thermometers, and the Measurement of Temperature with these Instruments.—M. Bosscha.—The author answers the objections made by M. Regnault, and states that the paper of the latter does not teach anything certain on the indications of the thermometer between 0° and 100°; that M. Regnault considers that differences of 0·2° to 0·3° are insignificant quantities, which are too difficult to estimate, and may be neglected. The greater part of this paper is devoted to the question of the influence of peculiar kinds of glass on thermometers constructed with them.

Remarks on some Matters Relating to Spectrum Analysis.—M. Lecoq de Boisbaudran.—The author, in this paper, gives a preliminary account of the spectrum of the aureola emitted by the positive pole, that of the blue light of the negative pole, and that of the tail of fire (*trait de feu*). It being the author's intention to publish a memoir on this subject, we confine our abstract to this enumeration of contents.

Illumination of Transparent Substances.—M. Soret.—This paper contains, chiefly, observations on the labours made on this subject by M. Lallern, and there is attached to it a short note by M. Chevreul, who points out, in reference to observations made by the author as to the great difficulty of obtaining perfectly pure water, and the effect of that fluid upon glass vessels, that, as far back as the year 1811, he (M. Chevreul) found ammonia in all waters, however carefully distilled, and, besides this, he found it invariably to contain alkaline silicates, derived from its action upon glass, which is, even at comparatively low temperatures, acted upon by water. The eminent *savant* states that the bottles in use in his laboratory are made of green glass, which does not contain lead, and is better fit to resist the action of water, as well as of chemicals.

Researches on the Action of Contact (Catalytic Force of Berzelius).—M. Dubrunfaut.

Normal Quantity of Sugar contained in Wine.—M. Petit.—The author states that he has tested several samples of Bordeaux, Burgundy, Cahors wines, and wines produced in the Departments of du Cher, de la Loire, and de l'Indre, and found that the quantity of sugar contained therein varies from 5 to 0·5 grms. to the litre of wine. No sugar could be detected in old wines. The quantitative estimation of sugar in these fluids is done by the author in the previously decolourised wines (by means of filtration through animal charcoal), and treating the filtered liquid with the well-known Fehling reagent. The sugar may be obtained in the separate state by saturating the wine with lime-water, evaporating to dryness, and treating the residue with alco-

hol at 40° (95 per cent). The sugar is left, on evaporation of the alcohol, and may be used for controlling the Fehling test by means of fermentation.

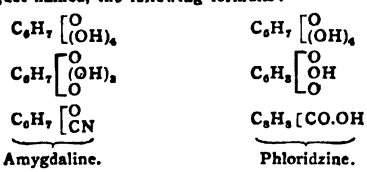
Chemical Composition of Fossil-Bones.—M. Scheurer-Kestner.—This very interesting and lengthy paper contains a series of results of analysis obtained by the investigation of fossil-bones of mammoth horses, and of bones of human skeletons belonging to the earlier centuries of our era. The author points out and proves that chemical analysis can decide the question of the respective ages of bones of various animals found mixed up together, and thus prove that these beings have not necessarily been contemporaneous with each other. This paper contains a large number of tabulated results of analysis made with the special view to careful estimation of the organic matter contained in the various bones. As instances, we quote the following, expressed in 100 parts:—Parietal human bone—Ordinary osseine, 3·1; osseine, soluble in dilute HCl, 12·3; water, 6·0; silica, 3·5; bone-earth (phosphate and carbonate of lime), 74·4. Fossil-horse—Ordinary osseine, 3·9; soluble osseine, 9·3; water, 6·8; silica, 0·3; bone-earth, 79·3. Mammoth bones—Ordinary osseine, 2·8; soluble osseine, 8·9; water, 5·7; silica, 12·4; bone-earth, 70·1. These bones were found in the Lehm, near Colmar, Bas-Rhin.

December 13, 1869.

This number contains the following papers relating to chemistry and allied sciences:—

The Siderostat.—M. Leon Foucault.—This paper belongs strictly to astronomy, but the reason why we notice it is that it opens with a brief, but well-deserved observation, bearing testimony to the great value set by His Majesty the Emperor of the French upon science, and the aid given by him, and from his private funds, to promote the labours of scientific men in general, and in this special case to cause, at his expense, the continuation and publishing of the works of the deceased *savant* named at the head of this paragraph.

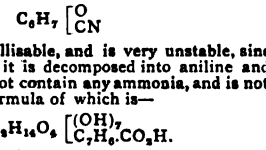
Constitution of Amygdaline and Phloridzine.—M. H. Schiff.—The author states that when he published a paper on arbutine, he briefly alluded to the subject of this paper, and gives, for the two substances just named, the following formulæ:—



Amygdaline. Phloridzine.

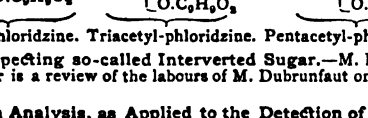
When amygdaline is treated with boiling anhydrous acetic acid, there is formed an heptacetylous amygdaline—

It is a solid substance, crystallising in needle-shaped crystals; amygdaline does not contain benzoyl, (C_7H_5O). When amygdaline is treated with aniline, which only acts upon the former at a temperature of between 160° and 180°, there is formed amygdaline-anilide—



This anilide is not crystallisable, and is very unstable, since, by the addition of boiling water, it is decomposed into aniline and amygdaline. Amygdaline does not contain any ammonia, and is not an amide of amygdalic acid, the formula of which is—

When anhydrous acetic acid acts upon phloridzine, three acetylated derivatives are obtained; one of these is crystalline, the two others are amorphous; they are represented by the following formulæ:—



Acetyl-phloridzine. Triacetyl-phloridzine. Pentacetyl-phloridzine.

Facts respecting so-called Interverted Sugar.—M. Maumené.—This paper is a review of the labours of M. Dubrunfaut on this subject.

Spectrum Analysis, as Applied to the Detection of Gaseous Substances, either when Single or Mixed.—M. Dubrunfaut.—This paper is not suited for useful abstraction; we may give it in full at a future period.

Analysis of the Morallon Kind of Emerald from the Muso Mines (New Granada).—M. Boussingault.—In the carburated schist of Iteco two kinds of emeralds are met with, designated by the appellation *canutillos*, crystallised emeralds always of great value, and *morallones*, amorphous and often fissured stones; of the latter kind the author has had a kilo. to experiment with akin to the first-named species; the colour of the latter varies from very deep green to very pale green, but the morallones are hardly transparent at all. Their sp. gr. is 2·64. On being submitted to strong heat, the loss per cent is 1·92. The analysis of this mineral has, at various periods, given rise, the author states, to some controversy. The older chemists considered that the colour was solely due to metallic oxides. But M. Loewy obtained a large proportion of carbonic acid when he ignited this mineral (the canutillo as well as morallon kind) in a current of oxygen; and he therefore concluded that the colour was due to organic matter. But M. Woehler and other German chemists saw that emeralds kept for an hour at the melting point of copper* did not change colour; and they detected the undeniable presence of oxide of chromium in this mineral. According to the author of this paper, the composition, in 100 parts, of the morallon emerald is:—Silica, 67·2; alumina, 19·4; glucina, 12·7; magnesia, 0·4; with traces of oxide of chromium and lime. Formula:—$Al_2O_3,2SiO_2+GlO_2,2SiO_2$.

Moniteur Scientifique, No. 312, December 15, 1869.

This number, chiefly filled with a copious index, does not contain any original papers.

Les Mondes, December 9, 1869.

This number contains the following original papers:—

Phosphorescence of the Sea.—M. Duchemin.—This phenomenon, the cause of which has given rise to much speculative discussion, has been thoroughly investigated by the author, who has been occupied with this subject for four years. The results arrived at may be summarised as follows:—The phosphorescence of the sea is solely due to the presence of myriads of very small infusoria (*Noctiluca miliaris*). These animalculæ emit light, produce phosphorescence, whenever they are agitated, either by mechanical means, by heat not exceeding 39°, for a temperature of 41° kills the animals, and after their death neither electricity, nor the action of cold or alcohol, or the addition of an acid to the sea-water, again brings about the phosphorescence. These infusoria are not killed by a strong degree of cold, which seems rather to excite the phosphorescence. An addition of 50 per cent of fresh water to the sea water does not affect the infusoria, but if they are placed in entirely fresh water they are killled. The addition to sea water of alcohol and any dilute acid for a moment greatly excites the infusoria, and a brilliant phosphorescence is the consequence; but the experiment is fatal to them. When the infusoria are kept in perfect darkness for more than a fortnight, they still preserve their faculty of phosphorescence. Electric currents do not kill these beings, which, according to the author, cause to those bathing in the sea sometimes a peculiar exanthema.

December 16, 1869.

Générateurs in explosibles (Steam-Boilers which cannot Explode).—MM. Belleville and Co.—This number contains the description, accompanied by several cuts, which merit the attention of all who have to work with steam, especially of high pressure.

Cosmos, December 4, 1869.

The number contains—

Properties of Vapours (Apparatus Bénévides).—M. Bénévides.—The apparatus, described and illustrated by a cut, is devised by the author with the view to prove the laws of ebullition, the phenomena of latent heat, the influence of temperature upon the tension of vapours, the mode of action of Giffard's injector, the cold produced by the expansion of very high pressure steam when blown off in the atmosphere, the action of steam as a motive power, and the transformation of the heat of combustion into mechanical force.

December 11, 1869.

Biography of Alexander von Humboldt.—Dr. C. Bruhns.—The author states that this work, of which he is the chief editor, will be published in the following manner:—The general scientific biography of the deceased eminent *savant* will be edited by MM. Avé-Lallemant, Dove, Loewenberg, and Foerster. The second section of the work will contain the following sub-divisions, to each of which the deceased contributed largely:—Meteorology and hydrography, Dr. Dove; physiology, Dr. du Bois Reymond; zoology, Dr. Carus; botany and botanical geography, Dr. Grisebach; geology and mineralogy, Dr. Ewald; geography, Dr. Peschel; astronomy and mathematical geography, Dr. Bruhns; natural philosophy and magnetism, Dr. Wiedermann; Humboldt considered as author, Dr. R. Gosche.

December 18, 1869.

Specific Gravity of the Water of the Black Sea.—M. Lapschine.—While the author, as commander of the Russian navy's corvette, *Lwitza* (*Lioness*), was engaged in taking soundings of the depth of the sea above named, he found, at latitude N. 44° 25′ 30″, longitude E. of Poulkowa, 7° 7′, the deepest place, amounting to 1020 toises

* According to the latest experiments made on this subject by Dr. van Riemsdijk, at the Utrecht Mint, pure copper, kept in a very slow current of pure and dry hydrogen, requires, for fusion, a temperature of 1330° C.

(1 toise = 6 feet and 6 and 9-10ths inches, English measure), the sp. gr. of the water at the surface of this spot was 0·013, while the water from the deeper portions of the sea varied in sp. gr. from 1·0151 to 1·0140. The figure 0·0130, just quoted, is exactly as in the original, but is, presumably, intended for 1·013.

Petroleum Sources near the Caspian Sea.—M. Meunier.—The existence of petroleum in this region of Asia has been known from a remote antiquity, but only of late has this material become utilised; and new borings, made according to the American system, have revealed the fact that, from a depth of 250 feet below the surface, petroleum is forced up so as to spout from 50 to 65 feet above the surface, and to yield quantities amounting to 19,000,000 lbs. annually, while 200,000 lbs. of solid paraffin are obtained from a kind of asphalte, very abundantly met with in this remote region.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale, October, 1869.

This number contains the following original papers relating to chemistry or allied sciences :—

Bronze Powder.—Dr. Wagner.—After referring to the history of the first application of the scraps and waste of what is commonly called tinsel, or Dutch gold (none of it was or is ever made in the Netherlands; this industry is confined almost entirely to Bavaria), the author treats of the mechanical means whereby the metal is brought to leaf and powder. There are three chief alloys in use, which are designated by the name of the colour, the composition of these being, in 100 parts :—For the light shade—copper, 83; zinc, 17; for the deeper shade—copper, from 90 to 94; zinc, from 10 to 6; for deep copper-red, no zinc at all. Copper may be obtained in finely-divided state by the following chemical means :—By igniting a mixture of chloride of copper, carbonate of soda, and sal ammoniac; by precipitating a solution of acetate of copper by means of sulphurous acid; by decomposing suboxide of copper by means of sulphuric acid; by electrolysis of a solution of sulphate of copper; by precipitating a solution of the last-named salt by means of a bar of iron wrapped up in filtering paper or coarse cotton tissue; but all the metal thus obtained is hard and crystalline, and unsuitable for the purposes it is intended for as bronze powder. The author found that, when oxide of copper, such as is used for elementary organic analysis, is submitted, hot, to the action of the vapours of ligroine (a light petroleum oil, or spirit), it is obtained in an excellent condition, and 100 kilos. of oxide require, for reduction at red heat, only 8 kilos. of ligroine.

Manufacture of Alcohol from Indian Corn.—M. Bergsträsser.—This paper is of interest only to distillers in countries where Indian corn is grown; the material is very suitable for the purpose, and the refuse remaining after distillation is a valuable food for milch cows, on account of the large quantity of fatty matter it contains.

Monatsberichte der Königlich Preussischen Akademie der Wissenschaften zu Berlin, July and August, 1869.

The papers on chemical subjects in these two numbers have been forestalled by having been published in other German periodicals, from which we abstracted them.

Bibliothèque Universelle et Revue Suisse.—Archives des Sciences Physiques et Naturelles, No. 143, 1869.

This number does not contain any original papers relating to chemistry or allied sciences.

Neues Jahrbuch für Pharmacie, von Dr. F. Vorwerk, October, 1869.

This number contains the following original papers:—

The Doctrines of Modern Chemistry.—Dr. Koller.—This paper contains a very clear review of the doctrines of modern chemistry, as compared with that of some years ago. The contents of this paper are divided into sections with the following headings:—Atomic and molecular weight; type and radical theory; substitution; anhydrides of acids; anhydrides of bases; salts, normal, basic, and acid. The paper is not well suited for useful abstraction.

On Gelatinæ Medicatæ.—Dr. Husemann.—This paper relates entirely to the pharmaceutical preparation of medicated gelatine lozenges.

Lithoreactive.—M. Weiss.—The author states that a mixture containing 5 per cent of sugar molasses, or beet-root syrup, 15 per cent of milk of lime (one part of slaked lime to three parts of water), and 80 per cent of caustic soda lye at 34° Beaumé, sp. gr. 1·039, is the best and surest means of preventing, as well as of breaking-up and dissolving, steam-boiler incrustations, while, moreover, this mixture is perfectly innocuous as regards its action upon either copper or iron. The hardest water only requires 1 kilo. of lithoreactive upon 1800 litres. of water.

Antimonoide.—M. Lichtenberger.—Under this curious name, there is in use a mixture for absorbing the protoxide of iron, while that metal is to be welded in red-hot state. The mixture consists of 4 parts of iron filings or turnings, 3 parts of borax, 2 parts of borate of peroxide of iron, and 1 part of water. The powder is made in the following manner:—To a solution of 3½ parts of borax in water, as much chloride of iron is added as is sufficient to obtain a precipitate of insoluble borate of peroxide of iron; this precipitate is washed upon a filter to remove common salt. This having been done, there is added to the precipitate (previously, of course, put in a suitable vessel) a solution of 3 parts of borax, and this mixture evaporated nearly to dryness, when there is added to it 4 parts of clean iron filings or turnings. The whole is then strongly dried and heated to incipient red-heat, whereby a fusion takes place; and, after cooling, the mass is pulverised.

NOTES AND QUERIES.

Electro-Deposition of Copper upon Cast-Iron.—(Answer to "Histrix.")—Among the many treatises on electro-metallurgy the "Repertorium der Galvanoplastik und Galvanostegie, &c.," von A. Martin, published at Vienna, is one of the best, and contains very ample information on this subject. This work can be inspected at the Patent Office Library.

Specific Gravity.—(Answer to "C. H. Parkin.")—According to Twaddell's scale, 0 is equal to 1000, or the specific gravity of distilled water, and each degree is equal to 0·005; so that by multiplying this number by the number of degrees marked on the scale, and adding 1·0 the real specific gravity is obtained. There are published tabular, forms giving the specific gravity for every degree of Twaddell's hydrometer.

Knife-Edges for Balances.—(1) Is a balance with agate edges as delicate in its indications, and as prompt in its action, as one with steel edges? [A balance with agate edges is as delicate in its indications, and as prompt in its action, as one with steel edges.]

(2) Is a balance with agate edges more liable to get out of order? [It is not so liable to get out of order.]

(3) If there be an advantage in the agate above the steel, is it worth the increased cost?—W. H. D. [Steel rusts in a damp atmosphere, or if kept in laboratory. Agate edges are well worth the extra cost.]

Treatment of Oils for Machinery Purposes.—(Answer to "B. S.")—Oils for machinery purposes, and for lubricating generally, may be purified by agitating them with from 4 to 8 per cent of their weight of a caustic soda lye, sp. gr. 1·2. After twenty-fours' repose, the supernatant oil is decanted from the soapy sediment, thoroughly washed with pure cold water, left to repose, again decanted, and filtered, best through some animal charcoal, such as is used for the filtration of sugar syrups in sugar refineries, and through the woollen tissue, also in use in these establishments. This treatment renders the oils very suitable for the purpose intended, and is quite free from any action on the metals.

Glue and Gelatine.—In reply to the enquiry of "G. G.," he will find every information in the admirable articles "On Gelatine and Glue," in Dr. William Allen Miller's "Elements of Chemistry," where the subject is thoroughly treated. I just add a test for the goodness of glue, which I have found very valuable. Assuming that "that" is the best glue which will take up most water—Take 50 grs. of the specimen, and dissolve it in 3 ozs. of water in a a water-bath. When dissolved, set it by fo 112 hours, to gelatinise; then take a 1 oz. chip box, place it on the surface of the gelatine, and put "shots" into the box, till it sinks down to a "mark" on the outside. It will be found that, the stronger the glue, the more shots it will take to sink the box down so that the mark shall be level with the surface of the gelatine. In a trial with Mitchell's glue, which is made here, and is the finest I ever met with, 50 grs. of glue, dissolved and gelatinised, with 3 ozs. of water, supported, to the mark on the box, 6 ozs. of shots, at a temperature of 58° F. On trying the same experiment with best Russian isinglass, 50 grs., dissolved in 3 ozs. of water, supported 9 ozs. of shots, the temperature being the same. Russian isinglass, therefore, is one-third stronger than glue in gelatinising power; but, as Russian isinglass is worth £84, and best glue is worth but £3, the cwt., there is no fear that the former will ever supersede the latter.—Alfred Bird, Birmingham.

MEETINGS FOR THE WEEK.

Tuesday, 28th.—Royal Institution, 3. Prof. Tyndall, "On Light." (Juvenile Lectures).

Thursday, 30th.—Royal Institution, 3. Prof. Tyndall, "On Light." (Juvenile Lectures).

Saturday, Jan. 1st, 1870.—Royal Institution, 3. Prof. Tyndall, "On Light." (Juvenile Lectures).

TO CORRESPONDENTS.

*** *Owing to our weekly Enclycopædic List of Foreign Papers connected with Chemistry and Physical Science having so materially enlarged the Contents of the* Chemical News, *we are compelled to issue the Index as a Supplementary Number. It has been compiled with great care, and with our copious abstracts of all the important papers, may be said to form an English edition of the "Jahresberichte." With the commencement of our new volume we intend to improve the appearance of the* Chemical News *by printing it on paper of a much better tone and quality.*

THE CHEMICAL NEWS.

VOL. XX. No. 527.

CAUSE OF BRIGHT LINE ON PARTIAL-PHASE ECLIPSE PICTURES.*

By Professor HENRY MORTON.

DURING the progress of the eclipse of August 7th, I observed on the negatives, taken during the partial phase by the section of my party with which I had located myself, a decided increase in the opacity of the silver deposit in immediate contact with the advancing edge of the moon. When, after our return to Philadelphia, all the negatives taken by the other two sections were handed over to me, I found the same characteristic appearance, varying only slightly in degree, to distinguish all of them, and this had, of course, been noticed by those engaged in making the pictures. In fact, many remarks have been made upon this point, and some deductions drawn from it.

On the paper prints prepared from these negatives this local density produced a line of light in contact with the moon's limb.

An appearance similar to this had been observed by Professor Alexander, in the photographs taken during the eclipse of 1860, as also by Mr. De la Rue, and while ascribed by Professor Challis and Professor Alexander to a very rare lunar atmosphere, had been explained by Mr. De la Rue and the Astronomer-Royal, as a subjective effect.

The Astronomer-Royal had, moreover, shown, in papers published in the *Monthly Notices* of the Royal Society, 1863, Nov. 13, and 1864, June 10, that no such effect would be produced by a lunar atmosphere, were it present. He, therefore, very justly discards such a supposition, and, by satisfactory experiments, shows that the light line in *the prints under his examination* is an optical illusion, and not an existing fact.

These experiments, however, when applied to good prints of our pictures, did not show the same result, and, beside, the actual opacity of the negatives seemed to preclude the above explanation as one accounting for the *entire* effect.

I therefore made the following experiment:—I converted one of the solar pictures, taken soon after first contact, into a crescent, by pasting partly over it a dark circular piece cut from another print. This showed a faint line of light, such as results from contrast, and which was no doubt found in the pictures examined by the Astronomer-Royal.

I then had this artificial eclipse-picture photographed (through the kindness of Mr. James Cremer), when negatives were produced showing a dense deposit along the lunar edge, and giving prints which showed a bright line in the same place, far more decided than that seen in the artificial original.

It thus appears that the effect observed in these eclipse pictures, while not due to any lunar inflection of sunlight, is also not due to an optical effect of contrast solely, but is, in great part, due to a chemical action, which may be explained by what we know of the chemical reactions concerned in the production of a negative.

It is well known that the development of a negative depends upon the presence of free nitrate of silver in the film, and that a great strengthening or intensifying may be produced by re-immersion in the silver bath, and a second application of the developer. Now, in the present case, part of the plate representing the dark edge of the moon, and, therefore, not acted upon, furnishes a reservoir of nitrate of silver, imbibed by the collodion film, which, during the development, penetrates for a short distance into the portion representing the *luminous* area of the sun whose supply of free nitrate was exhausted by the reaction which occurred at the first moment when the developer was applied.

My conclusion, then, is, that while a certain effect in the paper prints is, and was on former occasions, due to "contrast," yet, in the present instance, the peculiar appearance of the negatives, and most of that seen on the prints, is the result of a chemical action such as I have described, and does not represent any celestial phenomenon. The *appearance* of a bright line in the same place which has been noted by several observers is, we believe, due simply to the contrast of the sharply-defined lunar edge, which produces the faint line above mentioned, in the artificial eclipse picture before described.

* Communicated by the Author.

ON THE

CONSTITUTION OF THE COMPOUNDS OF SODIUM.

By J. ALFRED WANKLYN.

II.

IN this paper I propose to consider the function of sodium in the common compounds of the metal, and to enquire how far the ideas derived from the study of its organic compounds mentioned in the former paper are applicable to its common, well-known inorganic compounds.

Viewed in these organic compounds, sodium appeared as the representative—not of hydrogen, but of nitrogen; the task before me is, therefore, to represent, if possible, the inorganic sodium compounds as modelled on the plan of the compounds of nitrogen.

As I have already stated on various occasions, common salt admits of being looked upon as a sodium compound of the second order of complexity, thus:—

Cl Na‴ — — Na‴ Cl

and obviously a similar device might be applied to other well-known sodium compounds, such as the numerous soda salts.

I do not, however, propose to avail myself largely of a hypothesis of this kind on the present occasion, and am able to represent the metal as *unduplicated*, and, at the same time, trivalent in most of the compounds in question.

The following list of formulæ will speak for itself:—

Caustic soda	Na'''	$\begin{cases} O'' \\ H \end{cases}$
Nitrate of soda ..	Na'''	$\begin{cases} O'' \\ (NO_2)' \end{cases}$
Acetate of soda ..	Na'''	$\begin{cases} O'' \\ (C_2H_3O)' \end{cases}$
Sulphate of soda ..	Na'''	$\left\{ \begin{matrix} O'' \\ -(SO_2)''- \end{matrix} \right. \begin{matrix} \\ O'' \end{matrix} \left. \right\} Na'''$
Acid sulphate of soda	Na'''	$\begin{cases} O'' \\ -(SO_2'')-(OH) \end{cases}$
Bleaching soda ..	Na'''	$\begin{cases} (OCl)' \\ Cl \\ H \end{cases}$
Hypochlorite of soda	Na'''	$\begin{cases} O'' \\ Cl \end{cases}$
Sulphuretted soda	Na'''	$\begin{cases} S'' \\ H \end{cases}$
Common salt.. ..	Na'''	$\left\{ \begin{matrix} Cl \quad Cl \\ \text{———} \\ \text{———} \end{matrix} \right\} Na'''$, or Na_2Cl_2
Anhydrous oxide of sodium ..	Na'''	$\left\{ \begin{matrix} -O- \\ \text{———} \\ \text{———} \end{matrix} \right\} Na'''$, or Na_2O

Sulphuret of sodium $Na'''\left\{\begin{matrix}-S-\\ \\ \\ \end{matrix}\right\}Na'''$, or Na_2S

Bromide of sodium $Na'''\left\{\begin{matrix}Br\ Br\\ \\ \\ \end{matrix}\right\}Na'''$, or Na_2Br_2

Iodide of sodium .. $Na'''\left\{\begin{matrix}I\ \ I\\ \\ \\ \end{matrix}\right\}Na'''$, or Na_2I_2

Amide of sodium .. $Na'''\left\{\begin{matrix}(NH)''\\ H\end{matrix}\right.$

Nitride of sodium $(Na_3)'''N'''$

The list might be indefinitely extended, so as to exhibit the constitution of a host of double chlorides, bromides, and iodides. I will, however, content myself with formulating the Nessler reagent :—

$$Na'''\left\{\begin{matrix}(HgI)'\\ I\\ I\end{matrix}\right.$$

and will leave the rest to the imagination of my readers, who will find no difficulty in comprehending that to the new theory belongs the merit of rendering account of the vast number of double haloid compounds containing the alkali metals, which, according to the prevalent notion that the alkali metals are analogues of hydrogen, are regarded as mere freaks of nature, and as much as possible put out of sight.

Reverting to the new formula for caustic soda :—

The fact that caustic soda is volatile is an argument in favour of taking a single rather than a duplicate formula for that substance. (Possibly it will be found that when chloride of sodium seems to volatilise it really undergoes change into trichloride of sodium and metallic sodium—a view which is in harmony with various facts, notably, with the extraordinary power of chlorine to facilitate the volatilisation of metallic chlorides.)

According to the new theory, the action of sodium on water is as follows :—

$$Na''' + \left.\begin{matrix}H\\ H\end{matrix}\right\}O = HNa'''\left\{\begin{matrix}O + H\end{matrix}\right.$$

According to the theory at present in vogue, this reaction is thus :—

$$Na' + \left.\begin{matrix}H\\ H\end{matrix}\right\}O = \begin{matrix}H\\ Na'\end{matrix}\left\{\begin{matrix}O + H\end{matrix}\right.$$

The new theory, therefore, represents sodium as doing more than twice the amount of chemical work that is done by the metal according to the old theory. Instead of displacing one atom of hydrogen, sodium really displaces two atoms of hydrogen, and also combines with one of the displaced atoms. Hence the extraordinary quantity of heat generated by the action of alkali metals on water.

The ordinary theory of caustic soda, as a member of the water-type, is beset with difficulties and inconsistencies of many kinds. Why should caustic soda be so active a chemical reagent as it is? If alcohol and caustic soda be both of them built on the water-type, why should the former be so inactive and the latter so very active.

The new theory renders account of the energy of caustic soda. According to it this substance is, in one-third of its structure, the hydride of sodium, and, therefore, naturally endowed with abounding energy.

Berthelot's splendid discovery of the synthesis of formiate of soda is beautifully in harmony with the new theory :—

$$CO + Na'''\left\{\begin{matrix}O''\\ H\end{matrix}\right. = Na'''\left\{\begin{matrix}O''\\ COH\end{matrix}\right.$$

The production of bleaching soda, and, generally, oxidation under the influence of alkalies, are quite natural changes suggested by the very formulæ of the new theory :—

$$Cl_2 + Na'''\left.\begin{matrix}O''\\ H\end{matrix}\right\} = Na\left\{\begin{matrix}Cl\\ (OCl)'\\ H\end{matrix}\right.$$

ON SOME

TECHNICAL APPLICATIONS OF THE SPECTRUM MICROSCOPE.*

By H. C. SORBY, F.R.S., &c.

(Concluded from p. 306.)

On Some Adulterations of Malt Liquors.

I HAVE made very many experiments in order to ascertain how far the spectrum method can be employed in detecting adulterations in beer. Many of the substances used are added in such quantities, and impart so little colour, that there seems to be no chance of discovering them by their spectra. I have chiefly directed my attention to those employed as substitutes for hops, such as picric acid, gentian root, calumba root, and the entire plant of *Ophelia chireta*, commonly known by the more simple name of chiretta. So far I have not been able to detect any difference between the colouring matter of gentian, or chiretta, and hops. They all give the same reactions and spectra with the various reagents, or at least so nearly the same that there appears to be no chance of detecting them in the presence of the colouring matter of wort or beer. Calumba root, however, contains two colours, one of which is quite different from any that should occur in genuine malt liquors. The exterior part of the root is yellow, and water extracts from it a bright yellow colour. The interior part is browner, and does not contain this yellow, but a browner colour, which also occurs to some extent in the outer layer. On evaporating the aqueous solution to small bulk and re-dissolving in alcohol, this brown colour is left insoluble, but the bright yellow colour remains in the alcohol in a curiously turbid condition. The brown colour appears to be identical with that found in liquorice, and could not be detected by any of the reagents; but the yellow colour may be recognised, if beer has been adulterated by a moderate amount of calumba root. When dissolved in water or alcohol it is a very clear, bright yellow, but gives no well-defined spectrum. Ammonia makes it slightly orange, and when dissolved in sulphuric acid, it is the same bright yellow as in water. Oxidising reagents, such as hypochlorite of soda, produce no change in weak acid solutions; but when added to the solution in sulphuric acid they alter it into a deep red colour, changed into an orange-yellow by excess. Deoxidising reagents, such as hyposulphite of soda, restore the deep red to the original yellow. The most useful test in connection with the various other colours already described is hypochlorite of soda gradually added to the solution in sulphuric acid. This first makes it a deep red, giving the spectrum 3 . . 4 - —, and the addition of a little more produces scarcely any further change; but when large excess has been added it fades to an orange, giving the spectrum 6 . - 7 —. The colouring matter of fresh wort treated in the same manner is not turned at all red, and though the colour of finished beer is changed to red in a very similar manner, yet, after so much hypochlorite has been added as to turn it deep pink-red, a very little more makes it pale yellow. We may take advantage of this circumstance to detect calumba root.

In examining any suspected beer, it, and a similar quantity of genuine, should be evaporated in separate dishes, so that the results may be more accurately compared. The presence of calumba root is first somewhat betrayed by the fact of the resin, which separates on evaporation, being abnormally yellow, and when the syrup is dissolved in alcohol, and the solution evaporated to dryness, the purified colour is decidedly brighter yellow than it ought to be. Taking, then, two experiment cells, so much of the colour of the genuine beer should be dissolved in one—in

* Communicated by the author, having been published in the *Quarterly Journal of Microscopical Science*, vol. ix., new series, p. 358.

sulphuric acid—as to give a decided orange yellow, with a spectrum 5 . . 6 - - 7—; and in the other cell so much of the suspected material as to give a colour of about the same tint. In both cases, about one-fourth of the bulk of the liquid should be alcohol, so as to prevent the formation of any precipitate. Hypochlorite of soda should then be added very gradually, and in equal quantities to both, when at first both will change to red, having a pinker tint in the genuine. After so much has been added as to make both as dark as they can become, a little more will turn the genuine to a pale yellow, giving a spectrum 7 . . 8 - - 9—; whereas that containing calumba root will remain a fine red orange, with a spectrum 3½ . . 4½ - - 5—. If too large a quantity of the hypochlorite be added, the colour of the calumba root will change into a much paler yellow, scarcely differing from that in the case of genuine beer, and hence particular care must be taken to add it gradually, and in small quantities. By this means, the adulteration of beer with 2 ozs. of calumba root to the gallon may be detected with confidence; but much less than that would scarcely give reliable results, unless it were possible to examine the unfermented wort. The addition of the hypochlorite to genuine wort does not turn it at all red, and merely alters it to a pale yellow; whereas, if calumba be present, it turns it to a decided red.

Picric acid may be detected when present in no larger quantity than 1 grain to a gallon. When dissolved in water, it is of a bright yellow colour, and cuts off the blue end of the spectrum in a sufficiently well-defined manner, giving the spectrum 8½ . . . This is not changed by ammonia or citric acid, nor does hypochlorite of soda cause it to fade when added to an acid solution. The most striking change is that produced by the addition of sulphuric acid, which makes it so much paler that a couple of drops added to the aqueous solution in one of the small cells leaves it nearly colourless. In order to detect it in beer, about 1 oz. should be evaporated to dryness, and then re-dissolved in no more water than will make the solution sufficiently liquid to allow bubbles to rise readily through it. This should be introduced into a test-tube and agitated with ether, which dissolves out the greater part of the picric acid, but scarcely any colour, from genuine beer. Since it is very important to avoid contamination with any of the material not soluble in ether, it is well, in the first case, to use somewhat more than the bulk of the concentrated beer, and to transfer it to another *perfectly dry* test-tube, then agitate with a fresh quantity of ether and add it to the first, arranging so that the total amount of ether may fill a ½ inch test-tube to the depth of about 2 inches. After corking it up, it should be allowed to stand till quite clear, and till any particles not soluble in ether have adhered to the sides of the tube. The clear solution should then be poured off into another tube, water added so as to give a depth of about half an inch, and well agitated with the ether. After it has collected at the bottom, the ether should be removed by a pipette, the aqueous solution washed with a little fresh ether, and then evaporated to dryness. In the case of genuine beer the ether extracts scarcely any colour, and the greater part of this and the resinous matter afterwards remain in the ether, so that on evaporating the aqueous solution, which is scarcely coloured, a mere trace of a yellow colour is obtained, so free from resin that, when dissolved in water and a drop or two of alcohol added, we obtain a clear, very pale yellow solution, so pale that if one ounce of beer has been used, the spectrum is about 10 . . 11.—, changed to about 9 . . 10 - - 11 — by sulphuric acid. If, however, picric acid be present, the solution in ether is a decided clear bright yellow; the greater part of the colour is extracted from it by the water, and on evaporating to dryness more or less of a clear bright yellow is obtained. If as little as a grain per gallon were present, when dissolved in water with a drop of alcohol, a clear bright yellow solution would be obtained, giving the spectrum 8 . . . made much paler by the addition of sulphuric acid, which decolourises the picric acid, and merely shows the colour of the beer itself, which, if one ounce had been used, and all the product introduced into the experiment cell, would not be deeper than 9 . . 10 - - 11—, or very decidedly paler than what would be seen before the addition of sulphuric acid, if even less picric acid than one grain per gallon had been present in the beer.

I have not been able to discover any essential difference between the colouring matter of *Cocculus Indicus* and that of liquorice; and though it would be difficult to prove it in a positive manner, yet I think it very probable that a small quantity of this colouring matter is the cause of the brown colour of chiretta, and of the slightly brown tinge in hops. It would, therefore, be impossible to detect *Cocculus Indicus* in porter by means of its colouring matter, even if present in far larger amount than is ever likely to be the case.

Though the detection of turmeric in beer does not necessarily depend upon the spectrum microscope, yet the method employed is so closely related to our present subject that it may be well to describe it. The best test for its presence is the very strongly fluorescent character of the solution in benzol. The alcoholic solution is much less fluorescent. In order to be able to detect fluorescence and examine the spectrum of the dispersed light, I have found it very convenient to make use of cells about three-quarters of an inch deep, made out of moderately thick barometer tube, having an internal diameter of about one-sixth of an inch, cut square, and polished at one end, and melted up at the other, which is fixed into a small brass foot by means of black sealing-wax. On introducing a clear solution, covering it with a small piece of thin glass, illuminating the tube at the side by strong daylight, and looking down the axis, the liquid appears quite black, if it be not at all fluorescent, for no light is reflected from either the apparatus or the liquid; whereas, if fluorescent, it looks more or less opaque and of a colour depending on the nature of the substance. Such tubes can easily be placed on the stage of the microscope, and the spectrum observed, which, in some instances, is remarkable in showing one or more narrow bright bands.

In the case of turmeric, a very minute quantity dissolved in benzol gives a beautiful more or less blue-green fluorescence, with no special dark or bright bands. Half an ounce of the suspected beer should be evaporated to so small a bulk that it may occupy only about half an inch in the depth of a test-tube half an inch in diameter, and an equal amount of benzol added to it, with about an equal quantity of alcohol; since, without this last, the globules of benzol collect together with extreme slowness. After well agitating the whole, the tube should be set aside until the benzol has collected at the top, as a clear solution, which must then be introduced into one of the cells just described, by means of a pipette. In the case of pure beer, this solution is of a faint yellow colour, but is scarcely at all fluorescent. If no more than one grain of turmeric has been added to a gallon of beer, the fluorescence is so strong that it could not be seen to greater advantage, and even as little as one-tenth of a grain per gallon may be detected with confidence.

It will thus be seen that the spectrum method of study serves to throw considerable light on some of the changes that take place in the process of brewing, and would also enable us to detect the presence of some adulterations; but, at the same time, it would always be requisite to bear in mind that it is possible that some of the colouring matters I have described may themselves become altered when kept in solution for a considerable time.

Adulteration in Drugs, &c.—Mustard.

I now proceed to describe the detection of adulteration in a variety of substances. Having just explained the method to be employed when the presence of turmeric is suspected, it may perhaps be well to mention now all that need be said on that substance. Its presence may easily be detected in nearly all the ground mustard sold in the shops; and, as far as I am able to judge from the intensity

of the fluorescence, the amount varies from about one-third to one-half per cent.

The natural seeds contain a yellow colour soluble in water, which is the same as that found in many yellow leaves; another yellow colour, insoluble in water, but soluble in alcohol, which corresponds with the xanthophyll of yellow leaves; and there is also often present a small quantity of chlorophyll in the imperfectly ripe seeds. The powdered mustard should be digested in alcohol, about an equal quantity of water added, and the solution filtered. On agitating with benzol this rises to the top, with the colour of the turmeric in solution, which can be easily detected by its strong green fluorescence. Chlorophyll, if present, would give a red fluorescence, and by transmitted light, a spectrum with well-marked absorption bands.

Rhubarb.

The same process may be successfully employed in the case of rhubarb; and as small a quantity of tumeric as 1-10th per cent may be detected in no more than 2½ grains of rhubarb. There is not the least difficulty in distinguishing, by this means, inferior pale rhubarbs coloured by turmeric, so as to resemble those of the best quality.

The detection of small quantities of gamboge, added to increase the purgative action of these inferior kinds, is not so easy, and requires some care, especially in the presence of turmeric. The suspected powder should be placed on a small filter, and so little alcohol added as will give a few drops of clear solution, which would contain a comparatively large amount of the very soluble gamboge, and but little of the less soluble colour of the rhubarb itself. This alcoholic solution should then be agitated with bisulphide of carbon, and the supernatant alcoholic solution removed by means of a pipette and blotting-paper, and the solution in the bisulphide evaporated to dryness. This would contain a colour peculiar to the different kinds of rhubarb, and, perhaps, also turmeric and gamboge. If a small quantity dissolved in benzol gives the green fluorescent solution, turmeric is present; and, in order to detect the gamboge, it would then be requisite to re-dissolve in alcohol and add a little nitric acid, which so changes the colour of the turmeric that it is no longer removed by agitating with bisulphide of carbon; whilst the gamboge remains unchanged, and is abstracted by it from the alcoholic solution. After separating this, evaporating the bisulphide to dryness, and re-dissolving in alcohol, a small quantity of an alcoholic solution of iodine should be added, and then excess of ammonia, a little sulphite of soda, and a drop of water, to make it dissolve. This ensures the complete removal of any free iodine that may remain after the addition of ammonia.

In the case of pure rhubarb, this solution, when sufficiently but not too strong, has a decided pink colour, giving no well-marked absorption band in any part of the spectrum, but transmitting the blue rays very considerably better than the green; whereas, when gamboge is present to the extent of 2 per cent or upwards, the yellow colour due to it cuts off the blue light, and the solution is orange colour. The spectra are as follows:—

Pure rhubarb	4…8	9..10—11—
Rhubarb, with 2 per cent of gamboge	4…9	—10—
" " 4 "	4…8	—9—
Gamboge alone	7..8	—9—

In very many other cases, bisulphide of carbon is a most valuable reagent to separate different colours. An excess should be agitated with the alcoholic solution, when it sinks to the bottom, carrying with it the whole of some colours, and leaving the alcohol quite colourless. Other colours are only partially removed; whilst others are not abstracted in the least degree. These last are usually, but not always, those soluble in water; whereas, those easily removed are usually, if not always, insoluble in the liquid.

The cells for the examination of the spectra of solutions in bisulphide of carbon, ether, chloroform, or benzol, should be fixed to the glass plate by means of a mixture of glue and honey, made so as to be quite stiff, but yet to melt when warmed. Cells so cemented must be washed out with the liquids named above, and never with water or hydrous alcohol. The spectra of colours dissolved in the bisulphide are far more characteristic than when dissolved in any other liquid. So far, I have met with between two and three dozen different vegetable colours soluble in this reagent. The absorption bands are much farther removed from the blue end, when they occur in that part, so as to be far more distinct; and their position is not subject to variation from any change produced by evaporation, as in the case of ordinary alcohol, which may thus become more weak, and give the bands in a very different situation.

On the whole, the spectra are so characteristic and uniform that different colours, soluble in bisulphide of carbon, may usually be recognised in a very satisfactory manner by means of the spectrum of that solution alone; and this is fortunate, since such colours can seldom be distinguished by their behaviour with reagents. The dried colour must be dissolved in fresh bisulphide, since, when it separates from the alcohol, it contains some of that liquid in solution, which alters the position of the bands. As an illustration of what may be done, I give a few examples:—

Cheese.

Cheese of orange colour was digested in bisulphide of carbon, the solution washed by agitating with alcohol, and evaporated to dryness. On re-dissolving in alcohol diluted with a little water, a considerable amount of oily matter was separated; and, after evaporating the clear solution to dryness, and re-dissolving in bisulphide of carbon, it gave the spectrum 5½ 7½, which corresponds exactly with that of red annatto.

In all such experiments, it is requisite to use deep experiment cells (I use one 2½ inches deep), so that the amount of the bisulphide may be large in comparison with that of the oils, since the presence of much oil causes the bands to lie nearer the blue end, and thus interferes with the production of the characteristic spectrum.

Butter.

Treating yellow butter in a somewhat similar manner, I obtained the spectrum 6 7½. This differs entirely from that in the case of cheese, and corresponds with the spectrum of the colour of the exterior orange portion of carrots; but I am not quite certain whether this might not be derived from carrots eaten by the cows, though I am more strongly inclined to believe that it had been artificially introduced to increase the colour of the butter.

The difference between the spectra of the above-named colours and of various others closely allied to them will be better understood from the following table. In all cases they are those of the solutions in pure bisulphide of carbon:—

Red annatto	5½	7½
Exterior of carrot and the skins of several kinds of fruit	6	7½
Xanthophyll of many yellow leaves and flowers, and of the interior of carrots	6½	8
Colour of the petals of *Brassica* and of many other yellow flowers	6¾	8¾
Orange-yellow colour of turnip roots, and of the flowers of *Eryssimum Perofskianum*	5½	6¾ 8¾

It will thus be seen that these spectra differ from one another so much as clearly to show that they are due to different substances, which are often further distinguished by their different behaviour with bisulphide of carbon and alcohol, some being almost entirely, and others only very partially removed from the alcoholic solution by that reagent, so that they may be separated when two occur

mixed, as is not uncommon in some leaves and flowers. By first agitating the alcoholic solution with a little bisulphide, and washing this with alcohol, one may be procured nearly pure; and then, after agitating with a second small quantity of bisulphide and removing it, the other colour may be obtained nearly pure by evaporating the alcoholic solution to dryness, and dissolving the residue in bisulphide, which leaves indissoluble any of those numerous colours soluble in water which so commonly occur in leaves, flowers, and fruits. It is now nearly two years since I determined the existence of a considerable number of distinct substances, of which at least eight have lately been described by Dr. Thudichum.* under the general name of *leuteine*. I think that this new name can only be looked upon as something like the old term *xanthophyll*, as hitherto inaccurately employed for a whole series of yellow colours, some of which correspond with some of those included under *leuteine*. If it were thought desirable to have a generic name, the term *leuteine* might indeed be employed; but I must protest against the idea that the substances described as such by Dr. Thudichum are one single colouring matter. Some of their properties are indeed very similar, but that is often the case with those substances which give closely connected spectra, even when other facts show that they are entirely distinct, for there seems to be a sort of correlation between optical characters and chemical reactions; but this is no reason why we should confound together substances giving absorption-bands in distinctly different positions in similar solutions.

Saffron.

The adulteration of saffron with the sliced petals of the yellow crocus could easily be detected, even in a solution, by means of the remarkable spectrum of the latter, when the product of the action of bromine is deoxidised by sulphite or hyposulphite of soda. To the alcoholic solution of the colours soluble in water an aqueous solution of bromine should be added very gradually, until, after having become quite pale, it is made slightly yellow by the addition of more. Excess of ammonia and a little sulphite of soda should then be added. In the case of pure saffron the liquid remains almost or quite colourless, whereas ammonia first turns the colouring matter of the crocus to a red, which soon becomes yellow, and then sulphite of soda changes it to a remarkably fine red, which is highly fluorescent or red-orange colour, the spectrum showing a bright narrow band at about 3½. That of the transmitted light is very characteristic, and shows an excellent absorption band at 4½. On adding citric acid the colour becomes red-pink; it is still highly fluorescent, but of more yellow tint than before, the bright band being raised to about 4, and the absorption band in the spectrum of the transmitted light is raised to 5½: but the addition of hydrochloric acid destroys both the fluorescence and the absorption band. The only colour that I have met with analogous to this is one which occurs in the yellow flowers of several plants allied to the common wallflower (*Cherianthus Cheiri*), but the bands are in distinctly different positions. The production of the fluorescent colour is apparently due in both cases to deoxidisation, for even proto-sulphate of iron has the same effect as sulphite or hyposulphite of soda. If too much bromine be added, this change does not take place; but by a little care a small amount of the petals of the yellow crocus could be detected in a considerable quantity of saffron. The presence of safflower might be recognised by a similar process, but not so decidedly. After adding bromine and ammonia, it remains distinctly yellow, but gives no absorption band, whereas pure saffron is thereby quite decolourised.

Aloes.

I have tried a number of experiments in order to ascertain whether it would be possible to detect the adulteration of the socotrine aloes with the hæpatic, but have not yet succeeded in discovering any satisfactory method. It appears as if both contain the same general colouring matter, but the socotrine a second in addition. When ammonia is added to the alcoholic solutions, the socotrine gives a more orange colour than the hæpatic, and the green part of the spectrum is more absorbed; so that, when compared side by side, the spectra are—

Socotrine	4 ..	6½ — —
Hæpatic		6½ — —

It would, therefore, be possible to distinguish them from one another, or to detect the socotrine in the hæpatic, which is, however, the reverse of what would be likely to occur, since inferior things are not often adulterated with better.

Adulterations by means of Cochineal and Magenta.

Cochineal may be best detected in the tincture of roses by adding to the aqueous solution bicarbonate of ammonia and sulphite of soda. This changes the colour of the pure tincture to a very pale yellow, but that adulterated with cochineal to a light red. The spectra are somewhat thus:—

Pure tincture	8 ..	9 — — 10—
Adulterated with cochineal	3½ ..	7 — — 9—

The presence of magenta might be recognised by the spectrum of the solution in its natural state. The pure tincture shows no narrow absorption band in the green, whereas magenta gives a very distinct one, situated at 5 of my scale. In the case of the syrup of damsons and similar fruits, magenta may be detected, when in very small quantity, by agitating a dilute alcoholic solution with chloroform. If so much alcohol be added as only to partially dissolve the chloroform, scarcely a trace of the magenta is left in the alcoholic solution; and the characteristic spectrum can be easily seen by examining the chloroform, which scarcely abstracts any other colour. Ammonia produces no change in a solution of magenta in dilute alcohol; but the absorption band is immediately removed by a mere trace of sulphite of soda.

It would scarcely be a correct description of the facts to say that cochineal may easily be *detected* in pink-coloured confectionery, since, in some cases, its spectrum is seen to almost as great advantage as in any condition without any preparation, and it could generally be recognised with very little manipulation.

No doubt many other applications of methods similar to those I have described would present themselves to any one engaged in technical inquiries. I do not for one moment pretend to have exhausted the subject. I have merely examined various questions in order ascertain what methods might be employed with advantage; and I trust that the cases described above will, at all events, facilitate the application of this kind of qualitative analysis to practical questions; for I have met with many who were anxious to employ it, but had not sufficient time at command to make the preliminary experiments, which are so very necessary in all such inquiries.

Uses of Aluminate of Soda.—The white opaque glass (semi-porcelain) of which the French gas-globes are often made is manufactured in various ways. Hitherto, kryolite (fluoride of aluminium and sodium) has been found to answer best for the manufacture of the opaque white glass, but it seems now destined to be supplanted by aluminate of soda. In the application of the latter, no fluorine compounds are evolved which act very much on the substance of the melting pots. 1 cwt. aluminate of soda is equal to 1¼ cwts. kryolite and 1-10th cwt. calcined soda in the mixture for making that kind of glass. The aluminate, as manufactured by kryolite-soda makers, is quite free from iron, which is never the case with kryolite itself. Other applications of the new manufacture are in dyeing and print works; as a mordant in soap making, where white and heavy soap is required; in precipitating dyeing lakes, &c. Very likely the applications of this product will become more numerous as it becomes better known.

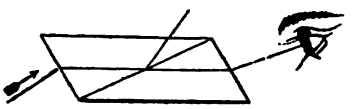
ON MICROSCOPICAL MANIPULATION.*

By W. T. SUFFOLK, F.R.M.S.

(Continued from p. 302.)

By an ingenious process, invented by Mr. Nicol, a crystal of Iceland spar is divided in the direction indicated in Fig. 35, and joined together again with

Fig. 35.†

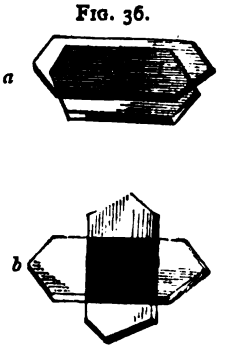


Canada balsam. This causes one of the rays to be so much refracted that it is thrown altogether out of view, and only one polarised ray is transmitted. This contrivance is known as the *single image* or *Nicol prism*, and is the means of polarisation most generally adopted for microscopical purposes.

Polarisation may also be effected by the use of thin slices of a mineral known as *tourmaline*. This crystal, when cut into thin plates parallel to the axis of the crystal, allows only the undulations in one plane to pass, the other being stopped. The cause of this action is, as yet, not understood. If two plates of tourmaline are superposed, and held before a strong light, it will be found that the light is alternately transmitted and stopped at every 90°, when one of the plates is rotated.

The same effect is produced, in a much greater degree, by using a pair of crystals of sulphate of iodoquinine, more commonly known as *Herapathite*, from its discoverer, the late Dr. William Bird Herapath. This salt is prepared by a tedious and complicated process, and described in a communication by Dr. Herapath to the Royal Society, and quoted in many microscopical works ("Micrographic Dictionary," second edition, p. 590). The obtaining of large regular crystals fit for polariscopes is a matter of great difficulty; and, unless the student is very expert in chemical manipulation, he is recommended not to attempt it. Small specimens fit for

Fig. 36.



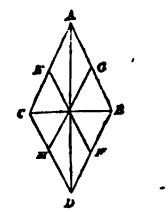
microscopical examination may, however, easily be made. This salt is the most powerful polarising agent known. If two crystals are superposed with their axes parallel (Fig. 36, *a*), light is readily transmitted; but, if the axes are crossed, as in *b*, the parts covering each other become perfectly opaque to transmitted light. This can easily be seen in a slide of the crystals mounted as a microscopical object, as some of the crystals are sure to be in this position.

The sky possesses the power of reflecting polarised light. If the observer stands with one shoulder directed to the sun, so that he faces a point 90° from it, and looks at a white cloud through a Nicol prism, he will find that the light reflected from the cloud is polarised, and that, as the prism is rotated, the cloud will alternately appear as a white cloud on a dark ground and a dark cloud on a light ground.

The effects here described may readily be seen without the special apparatus of mirrors, &c., by any one who has a microscope fitted with the usual polarising apparatus of two Nicol prisms. If the larger one, *the polariser* be put in its place below the stage, and the mirror so arranged that the light of a lamp or daylight be directed through it, it will be found, upon rotating the prism in its fitting, that no change is apparent, as the light, although polarised, is transmitted in every position of the prism. If the small prism, or *analyser*, be now put in its place, either over the object-glass or, better still, over the eye-piece, it will be found that the alternate transmissions and stoppages of light take place. If a film of *selenite* be now placed on the stage of the instrument, it will be found that the light will be coloured; and, when one of the prisms is rotated 90°, the colour will change to the complementary tint. For instance a film that transmits red light in one position of the prisms will transmit a green of such quality as to produce white light, were the two mixed. Blue would produce orange every quarter revolution; and so on through the other tints of the spectrum. Similar effects are produced by using films of mica, and all crystals possessing the property of double refraction.

To understand these changes of colour, it will be necessary to describe the direction of the axes of a crystal of selenite, which is represented in Fig. 37,

Fig. 37.*



A, D and C, B being the position of the depolarising axes, and E, F and C, H that of the optic axes. To understand the powers of these regions of the crystal, it will be necessary to try another experiment, which, although more advantageously shown with a large polariscope, can be done sufficiently well under the microscope. Let the film of selenite be so mounted as to be capable of rotation. If the stage of the microscope is capable of concentric rotation, no further contrivance is necessary. If the prisms now be arranged for the production of colour, and the selenite be slowly rotated, it will be observed that the colour gradually disappears. On continuing the rotation, it increases, and regains its intensity. If the amount of rotation is noticed, it will be found that the disappearances coincide with the position

* The substance of a course of lectures delivered to the members of the Quekett Microscopical Club, January—April, 1869.

† Pereira on "Polarised Light," published by Longmans and Co.

* Brooke's "Natural Philosophy," published by Churchill.

of the optic axes, E, F and G, H, and while the greatest intensity of colour is produced when the plane of polarisation passes through the depolarising axes, A, D and B, C. If the analyser be removed, no colours are to be seen; it is therefore evident that the analyser plays some important part in the production of these colours.

The selenite, being a doubly-refracting crystal, causes the ray of polarised light to be divided into two, which are, as usual, polarised in perpendicular planes, and, reaching the eye together, no colour is produced; but, if the analyser is added to the combination, the colourless image is broken up into two coloured ones, one only of which reaches the eye. If, instead of the Nicol prism, a contrivance known as the "double-image prism" be used, which will transmit both rays, but in a separate condition, the two images of complementary colours will be seen at once, and, if, by a suitable contrivance, they be made partially to overlap, the part where they join will be white, produced by the union of the two complementary tints.

The position of the optic axes may be easily observed in the corpuscles of starch and other polariscope objects which produce the well-known black cross, which indicates in a very marked manner the situation of these axes of no polarisation.

The apparatus employed for the examination of microscopical objects by means of polarised light consists of a *polariser*, *analyser*, and *retarding plate*.

The *polariser* is generally a Nicol prism, mounted so that it may be conveniently rotated; this is attached, by a suitable fitting, either beneath the stage, or, in large microscopes, to the sub-stage movement.

The *analyser* varies, being, according to circumstances, a Nicol prism, tourmaline, or Herapathite. The *Nicol prism* is the form of analyser generally used, and can be placed either over the eye-piece or within the body of the microscope above the object-glass; in the first position it has the advantages of being easily rotated, and of not interfering seriously with the definition of the magnified image; but, on the other hand, when used with any eye-pieces but those of the lowest power, it cuts off the margin of the field and reduces it to an injurious extent; this is owing to the prism by its thickness causing the removal of the eye to some distance from the eye-glass, although the Nicol prism, when intended for use as an analyser, is generally made as short as is consistent with efficient action. When the prism is placed within the body, it does not cut off any portion of the field, but the interposition of a dense substance, like Iceland spar, impairs the corrections and consequently the definition of the object-glass, and also causes some loss of light. It is much to be regretted that in many of the smaller microscopes no other provision is made for the placing of the analysing prism. When the binocular is used with polarised light, the analyser can be placed in no other position, and it is usually mounted in a short adapter so contrived that the prism can be easily rotated. It is well to have the means of using the analyser in both positions, that choice can be made of that best adapted to the kind of observation in progress; if very perfect definition is of less consequence than a field of full dimensions, as in viewing such objects as crystals, in which very little detail is to be seen, then the prism in the body may be employed with advantage; but should the formation of an image very perfect in its details be required, then the prism must be placed over the eye-piece.

Tourmaline, when it can be obtained of sufficiently pale colour, makes a good analyser, from its thinness it can be used over deep eye-pieces without cutting off the field; good stones are, however, scarce, and consequently expensive, as many light coloured specimens do not polarise well. The tourmaline is mounted in a brass cap similar to the one placed on the eye-piece, which is to be removed and the analyser substituted. Crystals of *Herapathite* polarise more powerfully, and are much lighter in colour than the palest specimens of tourmaline, and when they can be procured make very perfect analysers; they are extremely thin and do not interfere at all with definition, and are to be preferred in all delicate investigations. Where, however, total freedom from colour is a necessity, the Nicol prism, notwithstanding its other disadvantages, must be used.

The *retarding plate* or *selenite film* is commonly mounted, either on card, like an ordinary slide, or else in a brass plate, with a ledge to keep the object from slipping off; this is a very disadvantageous form, as the selenite cannot be rotated, while in a perfect polarising arrangement, every part, object included, should be capable of rotation. The most convenient and useful arrangement of selenites is that devised by the late Mr. Darker, in which a series of three discs are by combination made to give as many as thirteen different tints. In large microscopes having a substage, these selenites can be mounted so as to be capable of rotation either together or separately, and also allowing the selenites to be used or not, without disturbing the arrangement of the object on the stage.* These advantages have hitherto been confined to large microscopes; but Mr. Baily has so mounted a set of Darker's selenites for the author that they can be placed upon the stage in the ordinary manner, and at the same time allow of discs being added or withdrawn and rotated, without interfering with the object; the thickness of this stage plate is no more than is necessary to contain the three discs and allow them space to move, and all complicated machinery is dispensed with. The arrangement of Darker's system of selenites appears, at first sight, somewhat complicated, but is not so in reality, and the power of obtaining such a variety of coloured backgrounds is a very great advantage. The series consists of three discs, marked $\frac{1}{4}$, $\frac{1}{8}$, and $\frac{1}{2}$, which figures represent a certain amount of retarding influence upon the wave of polarised light and consequent colour production. Besides the figures just mentioned, each disc has engraved upon its mounting the mark P.A., meaning positive axis; when the selenites are superposed with these marks coincident, the effect is, that the power of one selenite is added to that of the other; for example, if the $\frac{1}{4}$, and $\frac{1}{8}$ discs are so placed, the power will correspond to the sum of the numbers, viz, $\frac{3}{8}$, but if the $\frac{1}{4}$ be turned round 90° then the $\frac{1}{8}$ will have only a power of $\frac{1}{8}$, the crossed position of the $\frac{1}{4}$ subtracting instead of adding its power to the $\frac{1}{8}$. The experiments with selenite films already described will have prepared the student to understand the cause of this; it will be recollected that the colour disappeared when the selenite passed through one of the optic axes

* A very perfect polarising apparatus is described by Mr. J. J. Field, *Journal of the Quekett Microscopical Club*, vol., p. 215; also in *Monthly Microscopical Journal*, vol. ii., p. 276.

of the selenite, provided the position of the prisms remained the same. If, instead of moving the disc 90° it be only moved 45°, the effect will be to neutralise; instead of giving a negative power the result will be the same as if the selenite were withdrawn. The following table, of the arrangement of Darker's selenites may be useful to those who possess the series. The colours vary somewhat in different sets, so the table must be made out by each observer for his own use. The colours in the following table are those given by Richard Beck in his work on "The Microscope:"—

	Prisms at right angles.	Complementary tint.
1. ¼ by itself ..	Very light lavender.	Straw colour.
2. ¾ − ¼	Darker do.	Light yellow.
3. ¾ by itself ..	Deep blue.	Light maize.
4. ¾ + ¼	Very light blue.	Orange.
5. ¾ − ¾ − ¼ ..	Lake.	Emerald green.
6. ¾ − ¾	Deep blue.	Bright yellow.
7. ¾ − ¾ + ¼ ..	Light green.	Light purple.
8. ¾ − ¼	Light plum colour.	Pea green.
9. ¾ by itself ..	Blue green.	Salmon.
10. ¾ + ¼	Green yellow.	Mauve.
11. ¾ + ¾ − ¼ ..	Pink light.	Green.
12. ¾ + ¾	Light pink.	Deep green.
13. ¾ + ¾ + ¼ ..	Very light red.	Stone green.

(To be continued.)

PROCEEDINGS OF SOCIETIES.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

Ordinary Meeting, December 14, 1869.

J. P. Joule, LL.D., F.R.S., &c., President, in the Chair.

Sir Charles Lyell, Bart., LL.D., D.C.L., F.R.S., &c., and Henry Clifton Sorby, F.R.S., F.G.S., were elected Honorary Members of the Society. Mr. Robert Routledge was elected an Ordinary Member.

Mr. William Boyd Dawkins, F.R.S., exhibited some old mining tools, brought over by Mr. Bauerman from the turquoise mines of the promontory of Sinai, consisting of a stone-hammer and rude splinters of flint. The turquoises occur in a bed of a quartzose mottled sandstone, in Wady Sidreh and Wady Maghara, in joints running, for the most part, north and south. They were worked, according to the evidence of the hieroglyphic inscriptions on the rock, by the Egyptians from the third to the thirteenth of the dynasties mentioned by Manetho. In and around the workings there are still the tools with which they were carried on. Innumerable splinters of flint, with their points blunted and rounded by use; stone-hammers, some of which are broken; and rounded pebbles, with a concavity on either side, caused by the friction of the thumb and finger, charged with particles of sand; and segments of small wooden cylinders, lie together. The flint flakes exactly coincide with the grooves in the rock made in the excavation, and evidently have been blunted by such use. The fragments of wooden cylinders are believed by Mr. Bauerman to have been portions of the sockets into which the flakes were fitted. The round pebbles were probably used for driving the rude chisel formed by the flint inserted into the wooden socket; while the large stone-hammers were used for breaking up the rock. There was no evidence that metal of any kind was used in the work. Mr. Bauerman also satisfied himself that the hieroglyphs were cut with implements similar to those used in the mining. This discovery is very important, because it opens up the question as to what tools the Egyptians used in working their wonderful monuments of granite and syenite. If it were worth their while to conduct turquoise mining with flint flakes in the Sinaiitic promontory, and if they used the same tools in the hieroglyphs that fix the date of these mines (and of this there can be no reasonable doubt), it is very probable that they employed the same means for the same end elsewhere, and that, to say the least, a part of their marvellously minute sculpture in Egypt has also been wrought with flint. There is no evidence that they were acquainted with the use of steel. Iron and bronze are not hard enough for the purpose. The minute and delicate sculpture left behind by the Mexicans, which can be proved to have been worked with stone tools, adds to the probability of this view.

NOTICES OF BOOKS.

A Pharmacopœia, Including the Outlines of Materia Medica and Therapeutics, for the Use of Practitioners and Students of Veterinary Medicine. By Richard V. Tuson, F.C.S., Professor of Chemistry and Materia Medica at the Royal Veterinary College. London: John Churchill and Sons. 1869. Pp. 311.

The preface informs us that this work is designed for the use of practitioners and students of veterinary medicine. The agents are arranged in alphabetical order, according to the plan adopted in the "British Pharmacopœia," and are treated of under the following heads:—(1) Latin Pharmaceutical Name; (2) English Pharmaceutical Name; (3) Synonyms; (4) Compositions; (5) Mode of Preparation; (6) Characters and Tests; (7) Actions and Uses; (8) Doses; (9) Modes of Application; (10) Incompatibles; (11) Antidotes; (12) Preparations. This work bears evidence of the progress of scientific veterinary medicine in this country, which has hitherto in this respect remained backward as compared with France, Belgium, and Germany, and last, but not least, with the Netherlands, where scientific veterinary medicine has replaced rude and clumsy empiricism and quackery since the middle of last century. Veterinary medicine requires in its practitioners an amount of tact and spirit of patient observation, which in some respects makes it as difficult a practice as that of the diseases of infants and young children. The book of Professor Tuson is carefully written, and is a valuable addition to the literature of the subject. It will be valued not only in this country, but in many parts of Europe, as well as in that great portion of America where the English language is widely used and known. The composition of bodies is expressed in modern atomic weights, a table of which, together with a list of the old ones, is appended. At page 24 we meet with Aër Chlori; it would have been better to write chlorium gasiforme, or gas chlorium. Aër is strictly limited to the atmospheric air we breathe, and if it is desired to express the state of aggregation of chlorine at all, it is best, we think, to use the word *gas*, first introduced by the well known Van Helmont; instead of *aërial* we should prefer gaseous. We notice with pleasure the excellent tables of weights and measures of the metrical system, and the relation of these weights to the British and *vice versâ*. The index to veterinary medicines, *arranged according to their actions and uses*, has been very carefully compiled, and it is a very useful feature therein that the Greek and Latin words have been properly explained and their derivation made clear. The work is well executed, being printed in a very clear and legible type, and has been carefully revised, since we have not, on perusing it, met with any clerical errors. We recommend the book with pleasure, and hope that veterinary medicine may rise, as it ought, in the estimation of scientific, and especially medical men, who should consider that the veterinary physician may exercise, by the proper attend-

ance to his calling, a great influence for the general public good. Seeing that that portion of *Police Science*, as Dr. H. von Mohl calls it, which is termed "Administration de la Sûreté et Salubrité Publique," is in this country an ill-defined and rudely digested chaotic mass, one cannot wonder that sufficient care has not been taken to assign to veterinary medicine its proper place and the social status it really deserves.

A Treatise on Asiatic Cholera. By C. MACNAMARA, Surgeon to the Calcutta Ophthalmic Hospital. London: John Churchill and Sons. 1870.

As may be expected from a medical man resident in the endemic area of cholera, this work contains very valuable information on a most difficult subject. From Section II., "On the Historical Account of Cholera," we learn what the Sanskrit writers have recorded on this subject; the translation given of an *historia morbi* by Susruta is highly interesting, and the more so to those who ever have witnessed patients attacked by Asiatic cholera, since they can hardly fail to observe the great resemblance this description bears to the reality; and from the vestige of a remote antiquity it would also appear that the disease has been in existence sporadically long before our era. The earliest notice of the existence of cholera in Hindostan, from the pen of a European, occurs in the "Lendas da India," by Gaspar Correa, in the year 1503; the entire chapter on the history of this disease is in every way interesting, and contains a great deal of hitherto unknown, or, at least, not well collected information. The section on the geographical distribution of cholera, and that on the bearing of meteorological influences upon the spread of this disease is also very valuable; the etiology of cholera is lucidly treated of, and the theories of Messrs. Bayer, Pettenkofer, Farr, and others, discussed in a clear manner. The value of the work is enhanced by the addition of several official reports, well executed maps, and statistical diagrams. As is usual with these publishers, this work is brought out in excellent style, and is a most valuable addition to the bibliography on this subject.

LABORATORY NOTES.

SULPHURETTED HYDROGEN APPARATUS.

THE following apparatus for the production of sulphuretted hydrogen, will perhaps be found useful.

It consists of a wide-mouthed bottle, A, fitted with a sound cork having two holes; through one hole a short glass tube (similar to the tube through which air is blown in a common wash-bottle) is passed, projecting into the bottle about ¼ inch.

A second smaller bottle, B,—one that can be lowered into A—is also fitted with a cork having two holes; through one a U-shaped tube is passed in such a manner that one end may touch the lower surface of the bottle A, and the other that of B, when one bottle is within the other. That portion of the tube which touches the lower surface of the big bottle should be of india-rubber, to prevent breakage.

The small bottle, with its cork and tube, should now be lowered into the bottle A, and through the remaining hole in each cork a tube is to be passed which shall project into the bottle B, about ¼ inch. All the holes through which the tubes pass should be lined with india-rubber tubing to render them air-tight.

To use the apparatus, remove the large cork, and it will necessarily bring away with it the small bottle with its tubes. Fill the bottle B, about three-fourths with acid sulph. dil.; fix its cork. Now place in the bottle A some sulphide of iron in lumps. Lower the small bottle till it rests on the bottom of A. Fix in the large cork. If air be now blown through the tube projecting into the bottle which contains the acid, the contents will be forced through the U-shaped tube into the bottle A, where it will mix with the sulphide of iron, and the gas will be evolved, which will escape through the tube opening into A. When sufficient gas has been obtained, by blowing through the tube by which the gas is escaping, the acid will again be forced through the U-shaped tube into A, and all action will cease. Powdered sulphide of iron must not be employed, because it would be carried back with the acid into the small bottle, where the action would be continued.

C. J. H. WARDEN.

Dec. 20th, 1869.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, *with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."*

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, December 20, 1869.

This number contains the following papers and memoirs relating to chemistry or sciences allied thereto:—

Distribution of Potassa and Soda in Plants.—M. Peligot.—This is a third paper on this subject, and the author treats in it the question whether plants have the faculty of absorbing the alkaline substances contained in the soil, and also whether they can, by any choice, assimilate the salts of potassa in preference to those of soda. The main points of this paper are:—(1) That soda is met with in plants in several distinct forms; this alkali is taken up by the radicles, penetrates into the tissues of the plants, and is found among the mineral matter left after incineration of the same. (2) In some marine plants, soda exists, in the form of salt water, in the sap which fills the tissues of these succulent vegetables. (3) All plants grown sufficiently near the sea-board contain chloride of sodium dispersed over their surface; but the presence of this salt in the ash of such plants does not imply that this salt has contributed to the development of the plants. The discussion of this paper gives rise to a statement of facts observed last autumn by M. Elie de Beaumont, who says that, while staying at Canon, Department du Calvados, and at a distance of 23 kilometres (about 14·3 English miles) from the coast, he observed that, during a severe W.S.W. gale, the leaves of the trees of that part of the country were, so to say, burnt up; and he ascribes this to the pulverised sea-water dust carried inland by this gale, proving that at a great distance from the coast sea-salt may be mechanically brought over.

Observations on the Communication of M. Soret, bearing upon the Illumination of Transparent Substances.—M. Lallemand.

Formation and Duration of Induced Currents.—M. Blaserna.—Both physico-mathematical papers.

Electro-Motor Force Developed by Platinum when it is brought into Contact with Various Liquids.—M. Gaugain.—The contents of this paper may be resumed as follows:—(1) That unplatinised platinum which is left for some time in an acid liquid is gradually modified, and thus becomes, after a shorter or longer lapse of time, more positive than it was at the moment of its first immersion. (2) That platinised or unplatinised platinum which is placed in an alkaline fluid becomes gradually more negative.

Researches on the Preparation and Purification of Sulphide of Carbon.—M. Sidot.—The chief results of the experiments made on this subject by the author prove that a full red heat is the best temperature for obtaining the largest quantity of sulphide of carbon from a given weight of sulphur in the state of vapour and charcoal. At a low red heat (*rouge sombre*), as well as at a bright red heat (*rouge vif*), the formation of this sulphide takes place, but the quantity obtained is by far smaller. As regards the purification, the author first re-distils the raw product, then shakes the distillate up with mercury, until the latter becomes black, and this operation is so long repeated as the metal is affected by the fluid, or, rather, by any sulphur dissolved in it. Sulphide of carbon thus purified is freed from the fœtid odour it generally has, and exhibits a smell of ether.

Composition of the Skin, the Modifications it undergoes by Tanning, and the Fermentation of Tannin in the Tan-Pits.—M. Müntz.—The author has investigated the skins and hides during the three principal stages of the operation of tanning it. In fresh

state, skin contains from two-thirds to three-fourths of its weight of water; dried at 110°, it becomes one of the most hygroscopical substances we are acquainted with. The immediate analysis of skin led to the following results for 100 parts:—Cellular tissue not acted upon by boiling water, 3·080; fatty matter, 1·058; mineral matter, 0·467; substances capable of forming gelatine, 95·395. During the tanning, the substance fixed in and upon the skin is not tannin, but a derivative thereof, which may be denominated tanning material (*matière tannante*), which differs from tannin in this respect—that it contains less oxygen and more hydrogen. The fermentation going on in the tan-pits takes place with exclusion of air, and gives rise to the formation of lactic, acetic, gallic, formic, and carbonic acids, while a small quantity of propionic acid is also formed.

An Error Committed in Saccharimetrical Estimations.—M. Maumené.—We intend to give a full translation of this paper at a future period.

Annalen der Chemie und Pharmacie, November, 1869.

This number contains the following original papers and memoirs:—

Balsam of Peru.—M. Kraut.—Among the substances originally only known and used in pharmacy, very few have given rise to such a number and such protracted investigations as the balsam just alluded to. The author of this paper has tried to reconcile, and bring into proper harmony, the researches of all his predecessors, and states that the oil of balsam of Peru (the cinnameine of Frémy) has been prepared by him by acting upon the original balsam with a mixture of ether and soda-lye containing about 4 per cent of soda. The ethereal solution is first washed, next deprived of the ether by distillation, and then the oil dried at 120° in a current of pure and dry hydrogen. By fractional distillation, this oil may be separated into three different portions:—(*a*) boils at 200°, and yields, on analysis, C_7H_8O; is converted into benzoic acid, without any evolution of carbonic acid, by the action of chromic acid. (*b*) boils at 300°, contains 79·09 per cent C and 6·0 per cent H, and was found to be benzoate of benzyl ether, a colourless fluid of the consistency of sweet oil of almonds; sp. gr. at 18·5°, 1·114; formula, $C_7H_7.O.C_7H_6O$. (*c*) boils at the boiling-point of mercury; sp. gr. at 23°, 1·050; this substance is cinnamate of benzyl ether—formula, $C_7H_7.O.C_9H_7O$; the dark-coloured residue remaining in the retort is styracine. When the oil, as originally obtained, is submitted to the action of caustic potassa dissolved in alcohol, and the resulting substances examined, the author found:—(*a*) Cinnamate of ethyl ether, $C_2H_5.O.C_9H_7O$; (*b*) benzyl alcohol, boiling at 206·2; sp. gr. at 19°, 1·0465; not solidified at −18°; formula, $C_7H_7.O.H$. The chief constituents of balsam of Peru are—Free cinnamic acid, resin, and the benzyl ethers of benzoic and cinnamic acid.

Action of Sulphurous Acid upon Chloride of Platinum.—M. Birnbaum.—When platino-chloride of ammonium is mixed with an aqueous and concentrated solution of sulphurous acid, care being taken to keep the latter in excess, a yellow solution is obtained which, on being concentrated by evaporation on a water-bath just to the point of crystallisation, and then further dried over sulphuric acid, after addition of some sulphurous acid solution, yields a salt—

$$Pt\left\{\begin{matrix}Cl\\HSO_3\end{matrix}\right\}+2NH_4Cl.$$

This compound is to be considered as a monobasic acid, a view fully confirmed by the fact that, instead of the two molecules of chloride of ammonium, chloride of potassium, or sulphate of ammonium can be taken up. The potassium salt is—

$$Pt\left\{\begin{matrix}Cl\\KSO_3\end{matrix}\right\}+2NH_4Cl.$$

When ammonio-chloride of platinum is treated with acid sulphite of ammonium, a salt is obtained—

$$Pt\left\{\begin{matrix}HSO_3\\HSO_3\end{matrix}\right\}+2NH_4Cl+H_2O.$$

Octyl Compounds.—M. Schorlemmer.

Derivatives of Propan.—M. Schorlemmer.

Action of Bromine upon Ether.—MM. Ladenburg and Wichelhaus.—The action of bromine upon compounds of organic origin is either a substitution or an addition, so that the halogen is found instead of H, or has become incorporated with the organic molecule, which is thereby saturated; but this action is not that commonly met with when bromine acts on the substances known as "ethers," since very frequently the halogen in these instances combines with the radical (*e.g.*, C_2H_5), and, while displacing O, causes an intrinsic change of the molecule. The authors have investigated this action more especially with Kay's ether (orthoformic ether), boiling between 146° and 148°; bromine acts upon this fluid, even at the ordinary temperature, forming bromide of ethyl and carbonic ether. The reaction of the halogen upon this orthoformic ether is represented by the following formula:—

$$2CH(OC_2H_5)_3+Br_2=$$
$$=2BrC_2H_5+CO(OC_2H_5)_2+CHO(OC_2H_5)+C_2H_6O.$$

The authors also investigated the action of bromine upon orthocarbonic, ethyl-glycolic, and ethyl-lactic ether.

Contribution to Our Knowledge of Selenium.—M. Rathke.—This monograph is divided into the following sections:—The allotropic modifications of selenium, and their relation to those of sulphur; sulpho selenium; seleno carbon; selenium-xanthogenic acid; experiments made for the purpose of forming selenium-tetrethyl and sulpho-tetrethyl; ethyl-selenious acid.

Preparation of Zinc Ethyl.—M. Rathke.—The preparation of zinc ethyl, according to the method suggested by MM. Beilstein and Alexeyeff, is rendered of far easier execution when there is added to the mixture of iodide of ethyl and zinc (with or without the addition of sodium amalgam) a small proportion of zinc ethyl from a former operation. The author states that the formation of zinc ethyl is thereby accelerated to such an extent as to admit of the entire operation being finished, by the aid of the heat of a water-bath, in half an hour. When 2 grms. of zinc ethyl are added to 100 grms. of iodide of ethyl, the action becomes sometimes so violent as to necessitate the withdrawal of the source of heat and cooling of the retort wherein that action takes place.

Di- and Tri-Chlorobenzoic Acid.—MM. Beilstein and Kuhlberg.—Tenth portion of a memoir on the subject of "Isomerism of the Benzoic Group." This portion of the monograph is divided into the following chapters:—Dichlorobenzoic acid from dichlorotoluol; dichlorobenzoic acid from benzoic acid; trichlorobenzoic acid from trichlorotoluol; alcohol of trichlorobenzoic acid, $C_6H_2Cl_3.CH_2HO$; trichlorobenzoic acid from benzoic acid.

Action of $SbCl_5$ upon Chloride of Toluol.—MM. Beilstein and Kuhlberg.—The authors, referring to a treatise they published in vol. CL. of this periodical (title not given), now state that when chlorine is passed into boiling tetra-chlorotoluol chloride, $C_6HCl_4.CH_2Cl$ (boiling-point, 296°), they obtained, by the fractional distillation of the products of this reaction, a fluid boiling at about 285°, from which, at 84°, crystals were deposited, which proved to be pentachlorobenzol, $C_7H_2Cl_5$. When trichlorotoluol is acted upon by chlorine at its boiling-point, the authors obtained therefrom a substance (tetrachlorobenzol) boiling at 240°, fusing at 140°; formula, $C_7H_2Cl_4$.

Toluchinones.—M. Borgmann.—Trichlorotoluchinon, $C_7H_4Cl_2O_2$, a solid substance exhibiting yellow-coloured crystals; difficultly soluble in cold, but more readily in boiling, alcohol; very readily soluble in ether and chloroform; and readily decomposed by heat. Trichlorotoluhydrochinon, $C_7H_4Cl_2O_2$.—Needle-shaped crystals, readily soluble in alcohol, and fusing at 212°. Biacetyltrichlorotoluhydrochinon—

$$C_6Cl_2\left\{\begin{matrix}CH_3\\O.C_2H_3O\\O.C_2H_3O\end{matrix}\right.$$

a crystalline solid, readily soluble in alcohol and ether, and fusing at 114°. Biethyltrichlorotoluhydrochinon—

$$C_6Cl_2\left\{\begin{matrix}CH_3\\O.C_2H_5\\O.C_2H_5\end{matrix}\right.$$

also a solid substance, fusing at 107°. Monochlorotoluhydrochinon-bisulpho acid—

$$C_6Cl\left\{\begin{matrix}CH_3\\OH\\OH\\(SO_3H)_2\end{matrix}\right.$$

a salt soluble in hot water, insoluble in alcohol, and crystallising in leafy-shaped crystals.

Supplementband, vol. vii., No. 1.

This number contains the following original papers and memoirs:—

On Mellitic Acid.—M. Baeyer.—From this very lengthy essay, we quote that mellitic acid was discovered by M. Klaproth, in a mineral called honeystone. The author refers, at some length to the researches made by MM. Wöhler, Liebig, Erdmann, Gerhardt, and others on this subject, and then states that, according to his own investigation, the most simple formula for mellitic acid is $C_{12}O_{12}H_6$; that is to say, that this acid is a benzol all the H of which has been replaced by the carboxyl group, CO.OH. This is fully proved by the fact that, when mellitic acid is decomposed in contact with soda-lime or lime at a high temperature, benzol and carbonic acid (carbonate of lime) are formed. This treatise is divided into the following sections:—Mellitic acid, which the author says is a sexbasic acid and a rare substance, since the mineral from which it is obtained is very sparingly found. Hydromellitic acid, $C_{12}O_{12}H_{12}$, also a sexbasic acid, obtained from mellitic acid by the action of sodium amalgam. Action of sulphuric acid upon hydromellitic acid, assisted by heat; the products of this action are carbonic acid, a quadribasic, and a tribasic aromatic acid—viz., isopyromellitic acid, $C_6H_2(CO_2H)_4$; and trimesinic acid, $C_6H_3(CO_2H)_3$. Hydroisopyromellitic acid, $C_{20}O_8H_{10}$. Hemimellitic acid, $C_9O_6H_6$. Pyromellitic acid, $C_{10}H_6O_8$. Hydropyromellitic acid, $C_{10}H_{10}O_8$. Action of sulphuric acid and heat upon hydropyromellitic acid. Trimellitic acid, $C_9H_6O_6$. Isohydromellitic acid, $C_{18}H_{18}O_{18}$. Action of sulphuric acid and heat upon isohydromellitic acid. Action of bromine upon hydromellitic acid. Benzol-carbon acids. Hydrobenzol-carbon acids. It should be mentioned that this paper is only the first part of the author's essay on this subject.

Indol.—M. Baeyer.—Indol can be obtained from indigo by two different methods—viz., by causing the vapours of oxindol to pass over heated powdered zinc; or, also, by heating, with the same metal, the yellow material obtained when indigo-blue is treated with tin and hydrochloric acid. From the author's statement, it appears, however, that indol is a substance which is difficultly prepared and very difficult to obtain in pure state. When pure, indol is a solid substance, soluble in water, crystallisable, fusing at 52°, and readily soluble in alcohol, ether, and hydrocarbons; it is a weak base, not forming salts very readily. Composition, in 100 parts:—C, 82·05; H, 5·98; N, 11·97. Formula, C_8H_7N. Indol is characterised by the peculiarity of producing red-coloured combinations. When the alcoholic solution of indol is mixed with hydrochloric acid, it tinges a piece of fir-wood placed therein cherry-red in a few minutes. The author states that

M. Kühne has found indol in the products of decomposition of the pancreatic juice.

New Method of Formation of Monobromacetic Acid.—Dr. Gloeckner.—The author describes, in this essay, a series of experiments made with bromethylen-bromide, $C_2H_2Br_2$, and obtained, especially by treating this substance in sealed tubes exposed to a higher temperature, and containing various substances (as, for instance, BaO, KaO, and water) along with the bromethylen-bromide, among other products, monobromacetic acid.

Action of the Haloids upon the Metallic Derivatives of some Carbon Compounds.—M. Bunge.—The author prepared silver succinimide by boiling pure succinimide with water and oxide of silver. The silver succinimide thus obtained was treated with iodine, and, by means of many carefully executed operations, crystals of pure iodide of succinimide were obtained. This compound is very prone to decomposition, especially when heated, since it cannot bear 100° without very perceptible alteration; it is readily soluble in aceton and water, but difficultly in alcohol and ether. The author obtained, with difficulty, some other compounds, but not in state of sufficient purity for analysis, and failed to substitute cyanogen for the atom of nitrogen which is combined with H in succinimide. Some experiments were also made relating to the action of vapours of bromine upon dried benzoate, oxalate, and succinate of silver; the products hereby obtained are bromobenzoic acid, bromide of silver, and succinic acid.

Zeitschrift für Chemie von Beilstein, No. 22, 1869.

The number contains the following original papers:—

On Cytisin.—Dr. A. Husemann.—This paper contains the account of some additional experiments on this subject, which was briefly abstracted by us from another paper (see CHEMICAL NEWS, vol. xx., p. 36). The formula of cytisin is $C_{20}H_{27}N_3O$; it fuses at 154·5°, and can be sublimed when the heat is properly regulated. The nitrate of this base, $C_{20}H_{27}N_3O,(HNO_3)_2+2H_2O$, is the only salt which crystallises well; it is soluble in water and dilute alcohol; its taste is far more bitter than that of the base itself. The hydrochlorate of cytisin, $C_{20}H_{27}N_3O,4HCl+3H_2O$, is a salt very soluble in water. With the following acids, cytisin yields deliquescent salts:—Sulphuric, phosphoric, formic, acetic, propionic, butyric, valerianic, oxalic, and tartaric. With the chlorides of platinum, gold, and mercury (bichloride), cytisin yields double salts, which can be obtained in crystalline state. Among the large number of reactions discovered by the author for the easy detection of this base, the most sensitive are:—A solution of iodine in iodide of potassium produces, even in the most dilute solutions of cytisin, a deep red-brown precipitate, which is at first amorphous, but becomes, when left standing, converted into beautiful transparent deep-red prisms. Bromine water produces, even in solutions containing only 1-150000th part of the base, a distinct cloudiness, and in more concentrated solutions, an orange-coloured precipitate. Chlorine water does not yield any precipitate or cloudiness at all. Cytisin is found in all parts of the well-known tree, *Cytisus laburnum, L.*, except in the wood; the ripe seeds contain a large quantity of this very dangerous substance, which is a poison, whether it be ingested into the alimentary apparatus or subcutaneously applied. From 3 to 5 decigrms. of cytisin, subcutaneously applied, will kill a large dog within half an hour.

On Isomeric Chlorotoluidines.—M. Wroblevsky.—When pure chlorotoluol is gradually treated with nitric acid (sp. gr., 1·475), the author succeeded in obtaining, after having twenty-six times repeated a fractional distillation, two nitro products, one of which boils at 245°, and the other at 253°; the sp. gr. of the former was found to be 1·307, and of the latter 1·325, both at 18°. The product boiling at 243° is designated by α, the product boiling at 253° by β; the formulæ are—α, $C_7H_6Cl(NO_2)$; β, $C_7H_6Cl(NO_2)$. Both bodies having been treated with fuming sulphuric acid, yield a sulpho acid; the baryta salt of that acid of the α kind is a readily crystallisable salt, rather difficultly soluble in water—formula, $(C_7H_5ClNO_2.SO_3)2Ba+4H_2O$; the baryta salt of the β kind is so readily soluble in water that it is impossible to obtain it in pure state. α chlorotoluidine, obtained from α $C_7H_6Cl(NO_2)$, by the action of Sn and HCl, is a fluid, sp. gr. at 20°, 1·185, boils at 238°, is not solidified at −14°, insoluble in water, and readily soluble in alcohol; β chlorotoluidine is a solid (when pure), crystallising in large foliated crystals, fuses at 38°, boils at 241°, almost insoluble in water, and readily soluble in alcohol. Both these substances yield crystallisable salts.

Contribution to the Knowledge of Sulpho-Nitrogen Acids (Schwefelstickstoffsäuren).—MM. Claus and Koch.—When neutral aqueous solutions of nitrite of potassa and sulphate of potassa are mixed together, there will be at first formed a cloudiness, or turbidity, shortly followed by the appearance of a quantity of needle-shaped crystals, while the solution becomes, simultaneously, distinctly alkaline to test paper. If concentrated solutions of the salts referred to are mixed, the reaction is finished in a couple of minutes, and the mass has become a thick magma, while, at the same time, the temperature of the mixture sometimes rises to 80°. The authors have investigated this salt, and studied many of its derivatives; the salt alluded to, tetrasulphammoniate of potassa (*tetrasulfammonsaures-kali*)—

$$K_4HNS_4O_{12}+3H_2O=4\left(S\begin{matrix}OK\\O_3\end{matrix}\right)^1\}.NH_3,$$

is formed according to the following equation:—

$$4(K_2SO_3)+KNO_2+3(H_2O)=5(KHO)+K_4HNS_4O_{12}.$$

The authors describe, at length, the mode of preparation and analysis of trisulphammoniate of potassa—

$$3\left(S\begin{matrix}OK\\O_3\end{matrix}\right).NH_3,$$

obtained from the foregoing salt by the action of water upon it according to the formula—

$$4\left(S\begin{matrix}OK\\O_3\end{matrix}\right).NH+H_2O=3\left(S\begin{matrix}OK\\O_3\end{matrix}\right).NH_3+KHSO_4,$$

of a disulphammoniate of potassa—

$$3\left(S\begin{matrix}OK\\O_3\end{matrix}\right).NH_3+H_2O=2\left(S\begin{matrix}OK\\O_3\end{matrix}\right).NH_3+KHSO_4.$$

The preparation and mode of analysis of these salts require very delicate manipulation.

Chemical Constitution of Pyroxiline (Gun Cotton).—Dr. Gintl.—The author states that when gun cotton, and also the collodion wool, are thoroughly moistened with concentrated sulphuric acid, after having been previously washed with water, so as to remove any matters present therein soluble in water, and left quietly standing in a well-closed suitable vessel, the substances will be dissolved and converted into a colourless, syrupy fluid. When this fluid is cautiously diluted with water, so as to prevent any increase of temperature, and next saturated with carbonate of baryta, and the excess of the latter salt, along with the sulphate of that base, are removed by filtration, there is obtained a perfectly colourless fluid, which, after having been evaporated *in vacuo* over sulphuric acid, leaves a gum-like mass, containing crystals of nitrate of baryta. The gum-like matter consists chiefly of the baryta salt of ligno-sulphuric acid (*holzschwefelsäure*), which may be obtained in free state by very cautious and careful removal of the baryta, by means of dilute sulphuric acid. Ligno-sulphuric acid was first discovered by Braconnot.

NOTES AND QUERIES.

Electrotyping Cast-Iron with Brass.—Can any of your readers kindly inform me if there is any known method of electrotyping cast-iron with brass?—E. B.

Dissolving Resin in Water.—Will any of your readers kindly inform me whether there is any process by which ordinary resin can be dissolved in water without losing its clearness and natural orange colour; and, if so, what the process is?—J. MILTON.

Analysis of Nitrous Oxide.—(Reply to "Veritas.")—Happening to possess a copy of Roscoe's "Elementary Chemistry," and looking over the article "Nitrous Oxide," I find he does not assert that, after analysis of the gas by potassium, in a bent tube over mercury, the products, after combustion of the metal in the gas, are nitrogen and potassium hydroxide, KHO; but he says that the products of the combustion are solid potassium oxide, or potash, and nitrogen.—W. K.

Native Carbonate of Baryta.—Will any of your readers kindly inform me, through the medium of your valuable paper, what are the principal applications of native carbonate of baryta, and what is about its market value?—A READER.

[Commercial value, according to purity, from 8s. to 9s. 6d. per cwt. Is applied for the manufacture of salts of baryta, for the preparation of caustic baryta, and also in glass-making.]

MEETINGS FOR THE WEEK.

MONDAY, Jan. 3rd.—Medical, 8.

TUESDAY, 4th.—Royal Institution, 3. Prof. Tyndall, "On Light." (Juvenile Lectures).

WEDNESDAY, 5th.—Pharmaceutical, 8.

THURSDAY, 6th.—Royal Institution, 3. Prof. Tyndall, "On Light." (Juvenile Lectures).
—— Royal, 8.30
—— Royal Society Club, 6.

FRIDAY, 7th.—Geologists' Association (Anniversary), 7.30.

SATURDAY, 8th, 1870.—Royal Institution, 3. Prof. Tyndall, "On Light." (Juvenile Lectures).

TO CORRESPONDENTS.

*** *Owing to our weekly Enclycopædic List of Foreign Papers connected with Chemistry and Physical Science having so materially enlarged the Contents of the* CHEMICAL NEWS, *we are compelled to issue the Index as a Supplementary Number. It has been compiled with great care, and with our copious abstracts of all the important papers, may be said to form an English edition of the "Jahresberichte." With the commencement of our new volume we intend to improve the appearance of the* CHEMICAL NEWS *by printing it on paper of a much better tone and quality.*

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give Instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

Instruction in Practical Chemistry for Students resident in the South of London.

Dr. JOHN MUTER, M.A.,

Continues to receive Pupils at his Laboratory, whom he instructs in all branches of Practical Chemistry on moderate terms.

Medical and Pharmaceutical Students successfully prepared for their Examinations in a short Course of Evening Lessons. Special Instruction, also, in the Microscopical and Chemical Examination of Articles of Food and Drink.

Every kind of Analysis Carefully and Promptly Executed. Analyses for the Profession at Half Fees.

NEW KENNINGTON INSTITUTE, 289, KENNINGTON ROAD.

Instruction in Practical Chemistry and Evening Classes for the Study of Chemistry, Botany, Materia Medica, &c.

TO PHARMACEUTICAL AND OTHER STUDENTS.

Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c., wishes to inform his old Pupils and others that he continues to devote his whole attention to Education.

The Session 1869—1870 will commence on the 4th of October, when Mr. BRAITHWAITE'S Laboratory, which has been enlarged, will be re-opened at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL and TOXICOLOGICAL CLASS meets as usual every Monday and Thursday evening, at 8 p.m., commencing October 4th.

The LATIN CLASS for the reading of the Pharmacopœia, Physicians' Prescriptions, &c., every Tuesday and Friday evening, at 8 p.m., commencing October 5th.

The BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday evening, at 8 p.m. The usual EXCURSIONS for the STUDY of PRACTICAL BOTANY will be continued every Saturday until further notice.

Fee to either of the above Classes, Half-a-Guinea per Month; to the Botanical Excursions only, Half-a-Guinea per Eight Lessons. Pupils can enter at any period.

Gentlemen Privately Prepared for the Examinations of the Pharmaceutical Society, &c., the "Special Examination for Chemists in Business," and for the "Modified Examination for Assistants."

All Fees must be payable in advance.

Letters of inquiry should be accompanied with a stamped envelope. Address, 54, Kentish Town Road, N.W.

Mr. Braithwaite receives a few Pupils to Board in his house.

Professor Tennant, F.G.S., will deliver a Course of Lectures on MINERALOGY applied to GEOLOGY and the ARTS, at King's College, London, on Wednesday and Friday mornings, at nine o'clock, during October, November, and December, commencing October 8th. Fee, £2 2s.

A Course of Lectures on MINERALOGY and GEOLOGY will also be delivered, on Thursday evenings, at eight o'clock. These begin October 14th, and will be continued to Easter, 1870. Fee, £1 11s. 6d. Professor Tennant gives PRIVATE INSTRUCTION in Mineralogy and Geology, Illustrated by a large number of Specimens, at his Residence, 149, Strand, W.C.

Methylated Spirits.—David Smith Kidd, Licensed Maker, Commercial Street, Shoreditch, N.E. Also FINISH, FUSEL OIL, and RECT. NAPHTHA.

Silicate of Soda in the state of Soluble glass, or in CONCENTRATED SOLUTION of first quality, suited for the manufacture of Soap and other purposes, supplied on best terms by W. GOSSAGE and Sons, Widnes Soapery, Warrington.

London Agents, CLARKE and COSTE, 19 and 20, Water Lane, Tower Street, E.C. who hold stock ready for delivery.

THOSE LADIES who have not yet tried the GLENFIELD STARCH, are respectfully solicited to give it a trial, and carefully follow out the directions printed on every package. It is rather more difficult to make than other Starches, but when this is overcome, they will say like the Queen's Laundress, that it is the finest Starch they have ever used.

SOLAR SPECTRUM.

Just published, price 7s. 6d.,

A Chromo-Lithograph of the Solar Spectrum (42 in. × 14 in.), containing upwards of Five Hundred Solar Lines.

To be had of

W. LADD,

MANUFACTURER OF SCIENTIFIC INSTRUMENTS,

11 and 12, BEAK STREET, REGENT STREET, W.

Light equal to Sun Light at any Time or Place

BY

J. SOLOMON'S PATENT MAGNESIUM LAMP.

It is adapted for Magic Lanterns. Cost per Hour Burning, 4s. Complete Apparatus for enlarging Photographs, £6 6s. od.

CATALOGUES ON APPLICATION AT

J. SOLOMON'S, 22, Red Lion Square, London.

MEDAL PARIS EXHIBITION, 1867.

AMSTERDAM EXHIBITION, 1869.

THE GRAND DIPLOMA OF HONOUR,

Being the First Prize, and superior to the Gold Medal.

Liebig Company's Extract of Meat.—*Paris Exhibition, 1867, Two Gold Medals; Havre Exhibition, 1868, The Gold Medal.*—Only sort warranted perfect and genuine by BARON LIEBIG, the Inventor.—"A success and a boon."—*Medical Press and Circular.* One pint of delicious beef tea for 2½d., which costs 1s. if made from fresh meat. Cheapest and finest flavoured "stock" for soups, &c.

CAUTION.—Require BARON LIEBIG'S signature upon every jar. Sold by all Italian Warehousemen, Grocers, Chemists, and Ship's Store Dealers.

All Wholesale Houses. And of LIEBIG'S EXTRACT OF MEAT COMPANY (LIMITED), 43, Mark Lane, E.C.

NOTICE.—Various chemical analyses have been published purporting to show a fraction more of moisture to exist in the Company's Extract than in some imitation sorts. It is extremely easy to evaporate the water almost to any extent; but it is quite as certain that the fine meaty flavour, which distinguishes the Company's Extract from all others, would be destroyed, if the concentration of the Extract were carried beyond a certain degree. Beef tea made from Liebig Company's Extract, with *boiling-hot water*, will be found to be greatly superior, in flavour, strength, and clearness, to any other sort. This explains the universal preference it obtains in the market.

This Extract is supplied to the British, French, Prusstan, Russian and other Governments.

Chloride of Calcium (Purified Muriate of Lime), total insoluble impurities under ½ per cent.

CHLORIDE OF BARIUM (Muriate of Baryta), free from Iron and Lead, total impurities, water excepted, under ½ per cent.

GASKELL, DEACON, & CO.,

ALKALI MANUFACTURERS, WIDNES, LANCASHIRE.

CHEMICAL APPARATUS.

German and French Glass, Berlin Porcelain, Accurately Graduated Apparatus, Metal and Wooden Apparatus of superior workmanship, Balances, Bottles, Pure Chemicals and Reagents, and every Laboratory requirement.

Catalogues free on application. Orders exceeding 40s. in value delivered free to any Railway Station in England.

MOTTERSHEAD AND CO.,

LABORATORY FURNISHERS,

1, MARKET PLACE, AND ST. MARY'S GATE,

MANCHESTER,

Water-glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEY'S, Ardwick Chemical Works, Manchester.

Unrivalled and Combined Entertainments for CHRISTMAS HOLIDAY Seekers.—Professor Pepper on A SHOCKING JAR.—THE NEUROCRYPT, or Woman of Nerve; a beautifully-modelled Automaton.—CHRISTMAS AND ITS CUSTOMS: Mr. Wardroper's Musical and Pictorial Entertainment. Illustrations—Christmas Fare and jovial old Father Christmas; the Yule Log; the Church decorated; the Squire's Seat; the Christmas Carols.—The MYSTERIES OF UDOLPHO. The Ghost Illusion perfected. Three emanating from one. Ghosts innumerable!—The ROYAL POLYTECHNIC'S change for One Shilling.

INDEX.

"ABRIDGMENTS of specifications relating to acids, alkalies, oxides, and salts, A.D. 1622—1866" (review), 116
